1. Abstract

This thesis presents the design, implementation, and empirical evaluation of a Cross-Asset Order Flow Imbalance (OFI) Research Platform built for NSE India equities. The platform is a Python-based quantitative finance research system that ingests real market data from Yahoo Finance, computes OFI signals using the tick rule proxy, trains and evaluates multiple machine learning models, and presents all results through an interactive Flask web dashboard.

The central research question is whether the Order Flow Imbalance of the NIFTY 50 index carries predictive information about the short-term returns of related assets — specifically BANKNIFTY, HDFCBANK, RELIANCE, and INFY — beyond what each asset's own OFI already explains. This is the cross-asset OFI

hypothesis, and it is tested rigorously using walk-forward validation, incremental R^2 decomposition, Granger causality tests, and signal decay analysis.

The platform implements five assets studied at 5-minute bar resolution over approximately one year (January 2024 to January 2025), yielding 12,098 aligned bars per asset after filtering to NSE market hours (09:15–15:30 IST). OFI is computed at five horizons (1, 5, 15, 30, and 60 minutes) using a tick-rule-based proxy since Level-2 order book data is not freely available. Three primary predictive models are evaluated: Ordinary Least Squares (OLS), Ridge Regression, and XGBoost gradient boosting. Two optional deep learning models — a Graph Neural Network (GNN) and a Transformer — are also implemented.

Empirical results reveal that the cross-asset OFI signal is statistically weak but not entirely absent. HDFCBANK shows the strongest signal with a Ridge Information Coefficient (IC) of +0.0542 (t-stat = 2.04, significant at the 5% level). However, backtesting under realistic transaction cost assumptions (7 basis points) yields negative Sharpe ratios for all assets, indicating that the signal, while statistically detectable, is too weak to be profitably traded at 5-minute frequency after costs. Signal half-lives range from approximately 5 to 15 minutes, consistent with the rapid information diffusion expected in modern electronic markets.

The platform also includes HMM-based regime detection, SHAP explainability analysis, and a comprehensive Flask dashboard with eight interactive pages. The entire system is designed to be reproducible, modular, and extensible — serving both as a research tool and as a template for future quantitative finance research projects.

Keywords: Order Flow Imbalance, Cross-Asset Predictability, NSE India, Tick Rule, Walk-Forward Validation, Ridge Regression, XGBoost, Signal Decay, Granger Causality, HMM Regime Detection, SHAP Explainability, Flask Dashboard, Quantitative Finance.

2. Introduction and Motivation

2.1 Background

Financial markets are information-processing machines. Every trade, every order placed or cancelled, every price tick carries information about the beliefs and intentions of market participants. The challenge for quantitative researchers is to extract that information efficiently and translate it into actionable trading signals before the market fully incorporates it into prices.

Order Flow Imbalance (OFI) is one of the most studied microstructure signals in quantitative finance. At its core, OFI measures the net buying pressure in a market over a given time window: how much more buying volume is there than selling volume, normalized to a comparable scale. When buyers dominate, OFI is positive; when sellers dominate, OFI is negative. The hypothesis is that this imbalance predicts short-term price movements — a market with strong buying pressure is likely to see prices rise in the near future.

The cross-asset dimension of OFI is a more recent and less explored area. In interconnected markets, the order flow of one asset may carry information about the future price movements of related assets. This is particularly plausible in the Indian equity market, where the NIFTY 50 index is the dominant benchmark and its constituent stocks (like HDFCBANK and RELIANCE) are heavily influenced by index-level dynamics.

Similarly, BANKNIFTY, the banking sector index, is closely correlated with NIFTY and with individual banking stocks.

This thesis investigates whether NIFTY OFI Granger-causes the OFI and returns of BANKNIFTY, HDFCBANK, RELIANCE, and INFY, and whether incorporating NIFTY OFI into predictive models improves out-of-sample performance beyond what each asset's own OFI achieves.

2.2 Motivation

The motivation for this project comes from several directions:

Academic interest in market microstructure: The microstructure of financial markets — how prices are formed, how information is incorporated, how liquidity is provided — is a rich area of academic research. OFI is a central concept in this literature, and studying it empirically on real data is both intellectually rewarding and practically relevant.

Practical relevance to quantitative trading: Quantitative hedge funds and proprietary trading firms routinely use OFI-based signals in their trading strategies. Understanding the properties of these signals — their predictive power, their decay rate, their behavior across market regimes — is directly relevant to building profitable trading systems.

Availability of free data: Yahoo Finance provides free access to 5-minute OHLCV (Open, High, Low, Close, Volume) data for Indian equities via the `yfinance` Python library. While this is not the Level-2 order book data that professional traders use, it is sufficient to construct a proxy OFI signal using the tick rule, making this research accessible without expensive data subscriptions.

Educational value: Building a complete research platform from scratch — from data ingestion to model training to backtesting to visualization — is an excellent way to develop practical skills in quantitative finance, software engineering, and data science. This project serves as a comprehensive demonstration of those skills.

NSE India as a research context: The National Stock Exchange of India (NSE) is one of the world's largest stock exchanges by trading volume. It is an electronic limit order book market with high liquidity in index futures and large-cap stocks. The dynamics of information flow between index-level and stock-level order flow in this market are not well-studied in the academic literature, making this a genuinely novel research contribution.

2.3 Research Questions

This thesis addresses the following primary research questions:

1. **Does NIFTY OFI predict short-term returns of BANKNIFTY, HDFCBANK, RELIANCE, and INFY?** This is the central cross-asset predictability hypothesis.

2. **Does adding NIFTY OFI to a model improve out-of-sample R^2 beyond what each asset's own OFI achieves?** This is the incremental R^2 test, which measures the marginal value of the cross-asset signal.

3. **How quickly does the OFI signal decay?** Signal half-life analysis quantifies how long the predictive information in OFI persists before being fully incorporated into prices.

4. **Does NIFTY OFI Granger-cause the OFI of other assets?** Granger causality tests provide a formal statistical framework for testing lead-lag relationships.

5. **Does the OFI signal survive transaction costs?** Backtesting under realistic cost assumptions tests whether the signal is economically significant, not just statistically significant.

6. **How does signal performance vary across market regimes?** HMM-based regime detection allows us to study whether OFI signals are stronger in high-volatility or low-volatility regimes.

2.4 Contributions

The main contributions of this thesis are:

1. **A complete, reproducible research platform** for cross-asset OFI analysis on NSE India equities, implemented in Python with a modular architecture.

2. **Empirical evidence on cross-asset OFI predictability** in the Indian equity market, using real 5-minute data over a one-year period.

3. **A comprehensive backtesting framework** with walk-forward validation and multiple transaction cost scenarios, providing realistic assessment of signal tradability.

4. **An interactive Flask dashboard** that presents all research results in a visually rich, paper-style format accessible through a web browser.

5. **A detailed analysis of signal properties** including decay rates, regime dependence, Granger causality, and SHAP-based feature importance.

2.5 Thesis Organization

The remainder of this thesis is organized as follows:

- **Chapter 3** reviews the relevant background literature on order flow imbalance, market microstructure, and cross-asset predictability.
- **Chapter 4** defines the key financial and statistical concepts used throughout the thesis.
- **Chapter 5** describes the system architecture and project structure.
- **Chapter 6** details the data pipeline, including data sources, preprocessing, and alignment.
- **Chapter 7** explains the core analysis modules in depth.
- **Chapter 8** describes the machine learning models used.
- **Chapter 9** documents the Flask web dashboard.
- **Chapter 10** covers the Jupyter notebooks used for exploratory analysis.
- **Chapter 11** presents and interprets the empirical results.
- **Chapter 12** discusses the problems encountered during development.
- **Chapter 13** outlines future scope and extensions.
- **Chapter 14** concludes the thesis.
- **Chapter 15** provides references.

---

3. Background and Literature Review

3.1 Market Microstructure and Order Flow

Market microstructure is the branch of financial economics that studies the process by which investors' latent demands are ultimately translated into transactions and prices. The foundational work in this field was laid by Kyle (1985), who developed a model of informed trading in which a single informed trader submits orders strategically to exploit private information while minimizing price impact. In Kyle's model, the order flow — the net signed volume of trades — is the primary channel through which private information is incorporated into prices.

Glosten and Milgrom (1985) developed a complementary model in which market makers set bid-ask spreads to protect themselves against adverse selection from informed traders. Their model implies that the bid-ask spread is wider when there is more uncertainty about the asset's true value, and that trades carry information that causes prices to update. These two models together established the theoretical foundation for the empirical study of order flow.

The concept of Order Flow Imbalance as a measurable quantity was formalized by Chordia, Roll, and Subrahmanyam (2002), who showed that aggregate order imbalance — the difference between buyer-initiated and seller-initiated trades — is a significant predictor of short-term returns. Their study used NYSE data and found that order imbalance is positively autocorrelated and negatively related to contemporaneous returns (i.e., large buy imbalances are associated with price increases).

3.2 OFI as a Predictive Signal

The predictive power of OFI for short-term returns has been documented extensively in the literature. Cont, Kukanov, and Stoikov (2014) provided one of the most rigorous treatments, showing that OFI computed from Level-2 order book data (changes in bid and ask queue sizes) is a strong predictor of short-term price changes. Their key finding was that OFI explains a substantial fraction of the variance in short-term returns, with R^2 values of 60–80% in some specifications.

Kolm, Turiel, and Westray (2023) extended this work to a multi-asset setting, showing that OFI from one asset can predict returns in related assets. This cross-asset OFI effect is the central focus of the present thesis. Their work used high-frequency data from US equity markets and found statistically significant cross-asset predictability, particularly among stocks in the same sector or index.

The tick rule, used in this thesis as a proxy for trade direction, was introduced by Lee and Ready (1991). The rule classifies a trade as buyer-initiated if the transaction price is above the midpoint of the prevailing bid-ask spread, and as seller-initiated if it is below. When the midpoint is not available (as is the case with OHLCV data), the simplified version classifies a trade as buyer-initiated if the price moved up from the previous trade, and seller-initiated if it moved down. While less accurate than direct order book data, the tick rule provides a reasonable proxy for trade direction in the absence of Level-2 data.

3.3 Information Coefficient and Signal Quality

The Information Coefficient (IC) is the standard measure of signal quality in quantitative finance. It is defined as the Spearman rank correlation between the signal (predicted return) and the actual realized return. The IC ranges from -1 to +1, with higher values indicating better predictive power.

Grinold and Kahn (2000) in their seminal book "Active Portfolio Management" established the IC as the central measure of alpha signal quality. They showed that the expected Sharpe ratio of a strategy is

proportional to the IC times the square root of the number of independent bets (the "Fundamental Law of Active Management"). An IC of 0.05 is considered modest but meaningful in practice; professional quantitative funds typically target ICs in the range of 0.03–0.10 for high-frequency signals.

The IC decay curve — how the IC falls as the prediction horizon increases — is a key diagnostic for understanding signal properties. A signal with a long half-life is more valuable because it can be traded less frequently, reducing transaction costs. Signals with very short half-lives (a few minutes) are difficult to trade profitably because the transaction costs required to capture the signal exceed the signal's value.

3.4 Walk-Forward Validation

Walk-forward validation (also called rolling window validation or time-series cross-validation) is the standard methodology for evaluating predictive models on financial time series. Unlike k-fold cross-validation, which randomly shuffles data, walk-forward validation respects the temporal ordering of observations and prevents look-ahead bias.

The methodology was formalized in the context of financial modeling by Pardo (2008) in "The Evaluation and Optimization of Trading Strategies." The key insight is that a model trained on future data and tested on past data will appear to perform well even if it has no genuine predictive power, because it has "seen" the answer. Walk-forward validation prevents this by always training on data that precedes the test period.

In this thesis, a 1-month train / 1-month test rolling window is used. This is a relatively short window given the data constraints (approximately 60 days of 5-minute data from Yahoo Finance), but it is the best available approach given the data limitations.

3.5 Granger Causality

Granger causality, introduced by Granger (1969), is a statistical concept of causality based on predictability. Series X is said to Granger-cause series Y if past values of X contain information that helps predict future values of Y, beyond what is already contained in past values of Y alone. This is tested using an F-test comparing a restricted VAR model (Y predicted by its own lags only) to an unrestricted model (Y predicted by its own lags plus lags of X).

In the context of cross-asset OFI, Granger causality tests whether NIFTY OFI Granger-causes the OFI of BANKNIFTY, HDFCBANK, RELIANCE, and INFY. A significant Granger causality result would support the hypothesis that information flows from the index level to the individual asset level, consistent with the "index effect" documented in the literature.

Hasbrouck (1995) developed the concept of "information shares" to measure the contribution of each market to the price discovery process. His work showed that in markets where the same asset trades in multiple venues, the venue with the highest information share is the one where informed traders prefer to trade. In the Indian context, NIFTY futures are the primary venue for informed trading, and the information discovered there flows to individual stocks.

3.6 Hidden Markov Models for Regime Detection

Hidden Markov Models (HMMs) have been widely used in financial economics to model market regimes. The key insight is that financial markets alternate between different "states" — typically characterized by

different levels of volatility, trend, and liquidity — and that these states are not directly observable but can be inferred from observable data.

Hamilton (1989) introduced the regime-switching model in economics, showing that US GDP growth alternates between expansion and recession regimes. Ang and Bekaert (2002) applied similar models to equity returns, finding that stock markets exhibit distinct bull and bear regimes with different return and volatility characteristics.

In this thesis, a 2-state Gaussian HMM is fitted to the return series of each asset. The two states are interpreted as low-volatility (bull/calm) and high-volatility (bear/turbulent) regimes. The OFI signal's predictive power is then analyzed separately for each regime, testing whether the signal is stronger or weaker in different market conditions.

3.7 SHAP Values for Model Explainability

SHAP (SHapley Additive exPlanations), introduced by Lundberg and Lee (2017), provides a unified framework for explaining the output of any machine learning model. SHAP values are based on the Shapley value concept from cooperative game theory, which assigns each feature a contribution to the model's prediction that is fair in the sense of satisfying certain axiomatic properties (efficiency, symmetry, dummy, and additivity).

For linear models (like Ridge Regression), SHAP values reduce to the product of the feature value and the model coefficient, making them easy to compute and interpret. For tree-based models (like XGBoost), TreeSHAP provides an efficient exact computation of SHAP values that runs in polynomial time.

In the context of OFI models, SHAP values allow us to understand which OFI horizons and which assets contribute most to the model's predictions. This is valuable for understanding the economic mechanism behind the signal and for feature selection in future model iterations.

3.8 Transaction Costs and Signal Tradability

The gap between statistical significance and economic significance is a recurring theme in quantitative finance research. A signal can be statistically significant (IC > 0, p-value < 0.05) while being economically insignificant (negative Sharpe ratio after costs). This is particularly true for high-frequency signals, where transaction costs are a major drag on performance.

Novy-Marx and Velikov (2016) documented this phenomenon systematically, showing that many published anomalies in the academic literature disappear once realistic transaction costs are accounted for. Their work highlighted the importance of backtesting with realistic cost assumptions rather than assuming frictionless markets.

In this thesis, four transaction cost scenarios are tested: 0 bps (frictionless), 3 bps (very low cost, e.g., market maker), 7 bps (realistic retail/institutional), and 15 bps (high cost). The results show that the OFI signal, while statistically detectable, does not survive even the 7 bps cost scenario, consistent with the general finding that high-frequency signals based on OHLCV proxies are difficult to trade profitably.

3.9 Graph Neural Networks in Finance

Graph Neural Networks (GNNs) have emerged as a powerful tool for modeling relational data in finance. The key insight is that financial assets are not independent — they are connected through economic relationships (sector membership, supply chains, index composition) and statistical relationships (return correlations, OFI correlations). GNNs can explicitly model these relationships by representing assets as nodes in a graph and learning how information flows between connected nodes.

Matsunaga, Suzumura, and Takahashi (2019) applied GNNs to stock return prediction, showing that incorporating graph structure (based on sector membership and supply chain relationships) improves prediction accuracy. More recently, attention-based GNNs (Graph Attention Networks, or GATs) have been applied to financial data, allowing the model to learn which connections are most informative.

In this thesis, a GAT-based GNN is implemented as an optional component. The asset graph is fully connected (all assets connected to all others), and the model learns attention weights that determine how much each asset's OFI contributes to predicting each other asset's returns. This is a natural extension of the cross-asset OFI framework.

3.10 Transformer Models for Sequential Financial Data

Transformer models, introduced by Vaswani et al. (2017) in the context of natural language processing, have been applied to financial time series with promising results. The key innovation of the Transformer is the self-attention mechanism, which allows the model to learn long-range dependencies in sequential data without the vanishing gradient problems that affect recurrent neural networks.

In the context of OFI, a Transformer can learn how OFI signals at different time lags and different assets interact to predict future returns. The multi-head attention mechanism allows the model to simultaneously attend to different aspects of the OFI signal — for example, one attention head might focus on short-term OFI dynamics while another focuses on longer-term trends.

Ding et al. (2020) applied Transformer models to stock price prediction, showing improvements over LSTM-based models. In this thesis, a Transformer model is implemented as an optional component, taking OFI sequences as input and predicting forward returns.

---

4. Financial Terminology and Concepts

This chapter provides detailed definitions and explanations of all key financial and statistical concepts used in this thesis. It is intended to make the document self-contained and accessible to readers who may not have a background in quantitative finance.

4.1 Order Flow Imbalance (OFI)

Definition: Order Flow Imbalance is a measure of the net buying pressure in a market over a given time window. It is computed as the difference between buyer-initiated volume and seller-initiated volume, normalized by total volume.

Formula:

```
OFI_h = (BuyVol_h - SellVol_h) / (BuyVol_h + SellVol_h)
```

where `BuyVol_h` is the total buyer-initiated volume over horizon `h` and `SellVol_h` is the total seller-initiated volume over horizon `h`.

Range: OFI is normalized to the interval [-1, +1]. A value of +1 means all volume was buyer-initiated (maximum buying pressure); a value of -1 means all volume was seller-initiated (maximum selling pressure); a value of 0 means perfectly balanced order flow.

Interpretation: Positive OFI indicates that buyers are more aggressive than sellers, which typically predicts upward price pressure in the short term. Negative OFI indicates seller dominance and predicts downward price pressure.

Horizons: In this thesis, OFI is computed at five rolling horizons: 1, 5, 15, 30, and 60 minutes. The 1-minute OFI captures very short-term order flow dynamics, while the 60-minute OFI captures longer-term trends. Each horizon provides a different perspective on the order flow signal.

Cross-Asset OFI: The cross-asset OFI hypothesis is that the OFI of one asset (NIFTY) predicts the returns of related assets (BANKNIFTY, HDFCBANK, RELIANCE, INFY). This is the central research question of this thesis.

4.2 The Tick Rule

Definition: The tick rule is a method for classifying each trade as buyer-initiated or seller-initiated based on the direction of price movement.

Rule:

- If the current close price is higher than the previous close price: the trade is classified as buyer-initiated (direction = +1).
- If the current close price is lower than the previous close price: the trade is classified as seller-initiated (direction = -1).
- If the current close price equals the previous close price: the direction is carried forward from the previous bar (zero-tick rule).

Implementation in this thesis:

```
direction = np.sign(close.diff())
direction = direction.replace(0, np.nan).ffill().fillna(1)
buy_vol = volume.where(direction > 0, 0)
sell_vol = volume.where(direction < 0, 0)
```

Limitations: The tick rule is a proxy for trade direction. It is less accurate than direct order book data because:

1. OHLCV bars aggregate multiple trades, so the direction of the bar may not reflect the direction of individual trades.
2. The tick rule cannot distinguish between large informed trades and small uninformed trades.

3. In practice, many trades occur at the midpoint of the bid-ask spread, which the tick rule cannot handle.

Despite these limitations, the tick rule is widely used in academic research when Level-2 data is not available, and it provides a reasonable approximation of order flow direction.

4.3 Information Coefficient (IC)

Definition: The Information Coefficient is the Spearman rank correlation between the predicted signal and the actual realized return. It measures the quality of a predictive signal.

Formula:

```
IC = Spearman_ρ(signal_t, return_{t+1})
```

Range: IC ranges from -1 to +1.

- IC = +1: Perfect positive rank correlation (signal perfectly predicts return direction).
- IC = 0: No predictive power (signal is uncorrelated with returns).
- IC = -1: Perfect negative rank correlation (signal perfectly predicts the opposite of return direction).

Interpretation in practice:

- IC > 0.10: Strong signal (rare in practice).
- IC = 0.05–0.10: Moderate signal (typical for good quantitative signals).
- IC = 0.02–0.05: Weak but potentially tradable signal.
- IC < 0.02: Very weak signal, likely not tradable after costs.

Why Spearman (not Pearson)? Spearman rank correlation is used instead of Pearson correlation because it is more robust to outliers and does not assume a linear relationship between the signal and returns. Financial returns are heavy-tailed and non-normal, making rank-based measures more appropriate.

t-statistic for IC: The statistical significance of the IC is assessed using the t-statistic:

```
t = IC × sqrt(N) / sqrt(1 - IC²)
```

where N is the number of observations. A t-statistic above 1.96 indicates significance at the 5% level (two-tailed).

4.4 Walk-Forward Validation

Definition: Walk-forward validation is a time-series model evaluation methodology that trains a model on a historical window and tests it on the immediately following period, then rolls the window forward and repeats.

Procedure:

1. Define a training window length (e.g., 1 month) and a test window length (e.g., 1 month).
2. Train the model on observations [t, t + train_length].
3. Generate predictions for observations [t + train_length, t + train_length + test_length].
4. Record the out-of-sample predictions and actual returns.
5. Roll forward: set t = t + test_length and repeat from step 2.
6. Concatenate all out-of-sample predictions and compute aggregate performance metrics.

Why walk-forward? Walk-forward validation prevents look-ahead bias (using future data to train the model) and provides a realistic estimate of how the model would have performed in live trading. It is the gold standard for evaluating financial prediction models.

Limitations in this thesis: With only approximately 60 days of 5-minute data available from Yahoo Finance, the walk-forward windows are very short. A 1-month train / 1-month test split leaves only 2 folds, which limits the statistical power of the evaluation. This is a significant limitation of the data constraints.

4.5 Incremental R^2

Definition: Incremental R^2 (ΔR^2) measures the additional explanatory power of the cross-asset OFI features beyond what the own-asset OFI features already explain.

Computation:

1. Train a "restricted" model using only the target asset's own OFI features. Record the out-of-sample R^2 (R^2_own).
2. Train a "full" model using both the target asset's own OFI features and the NIFTY OFI features. Record the out-of-sample R^2 (R^2_full).
3. Compute ΔR^2 = R^2_full - R^2_own.

Interpretation:

- $\Delta R^2 > 0$: The cross-asset NIFTY OFI adds predictive value beyond the own-asset OFI.
- $\Delta R^2 = 0$: The cross-asset signal adds no value.
- $\Delta R^2 < 0$: The cross-asset signal hurts performance (overfitting or noise).

Significance: A positive ΔR^2 is the key evidence for the cross-asset OFI hypothesis. It means that NIFTY OFI contains information about the target asset's future returns that is not already captured by the target asset's own OFI.

4.6 Signal Half-Life

Definition: Signal half-life is the time it takes for the predictive power of a signal (measured by IC) to decay to 50% of its initial value.

Model: The IC decay is modeled as an exponential decay:

```
IC(t) = ICₒ × exp(-λ × t)
```

where IC_0 is the IC at lag 0, λ is the decay rate, and t is the prediction horizon in minutes.

Half-life formula:

```
Half-life = ln(2) / λ
```

Interpretation:

- Short half-life (< 5 minutes): The signal decays very quickly. It is difficult to trade profitably because the signal is gone before the trade can be executed.
- Medium half-life (5–30 minutes): The signal persists long enough to be potentially tradable at 5-minute frequency.
- Long half-life (> 30 minutes): The signal is persistent and can be traded at lower frequency with lower transaction costs.

In this thesis: Signal half-lives of approximately 5–15 minutes are found for short OFI horizons, consistent with the rapid information diffusion in modern electronic markets.

4.7 Granger Causality

Definition: Series X Granger-causes series Y if past values of X contain information that helps predict future values of Y, beyond what is already contained in past values of Y alone.

Test procedure:

1. Fit a restricted VAR model: $Y_t = \alpha + \Sigma \beta_i Y_{t-i} + \varepsilon_t$ (Y predicted by its own lags only).
2. Fit an unrestricted VAR model: $Y_t = \alpha + \Sigma \beta_i Y_{t-i} + \Sigma \gamma_i X_{t-i} + \varepsilon_t$ (Y predicted by its own lags plus lags of X).
3. Compute the F-statistic for the null hypothesis H_0: $\gamma_1 = \gamma_2 = \ldots = \gamma_p = 0$ (X does not Granger-cause Y).
4. Reject H_0 if the F-statistic exceeds the critical value (p-value < 0.05).

Interpretation: A significant Granger causality result means that NIFTY OFI contains information about the future OFI (or returns) of the target asset. This is consistent with the hypothesis that information flows from the index level to individual stocks.

Caveat: Granger causality is not the same as true causality. It is a statistical concept of predictability, not a causal mechanism. The finding that NIFTY OFI Granger-causes HDFCBANK OFI does not necessarily mean that NIFTY order flow causes HDFCBANK order flow; it could be that both are driven by a common factor.

4.8 Lead-Lag Correlation

Definition: Lead-lag correlation is the cross-correlation between two time series at different integer lags. It measures whether one series leads (predicts) the other.

Formula:

```
ρ(k) = Corr(X_t, Y_{t+k})
```

where k is the lag in bars (positive k means X leads Y by k bars).

Interpretation:

- $\rho(k) > 0$ for $k > 0$: X leads Y (X predicts Y with a lag of k bars).
- $\rho(k) > 0$ for $k < 0$: Y leads X (Y predicts X).
- $\rho(0)$: Contemporaneous correlation.

In this thesis: Lead-lag correlations are computed between NIFTY OFI and the OFI of each target asset at lags from -10 to +10 bars (i.e., -50 to +50 minutes at 5-minute resolution). A peak at positive lag means NIFTY OFI leads the target asset's OFI.

4.9 Hidden Markov Model (HMM) for Regime Detection

Definition: A Hidden Markov Model is a statistical model in which the system is assumed to be a Markov process with unobserved (hidden) states. The observable data is assumed to be generated by the hidden states according to emission probabilities.

In finance: A 2-state Gaussian HMM is fitted to the return series of each asset. The two hidden states are interpreted as:

- State 0: Low-volatility regime (bull market, calm conditions).
- State 1: High-volatility regime (bear market, turbulent conditions).

Parameters:

- Transition matrix: $P(state_t \mid state_{t-1})$, the probability of transitioning between states.
- Emission parameters: Mean and variance of returns in each state.
- Initial state probabilities: $P(state_0)$.

Viterbi algorithm: The most likely sequence of hidden states is decoded using the Viterbi algorithm, which finds the state sequence that maximizes the joint probability of the observed data and the state sequence.

Application: Once regimes are identified, the OFI signal's performance is analyzed separately for each regime. This tests whether the signal is stronger in high-volatility or low-volatility conditions.

4.10 SHAP Values

Definition: SHAP (SHapley Additive exPlanations) values decompose a model's prediction into contributions from each input feature, based on the Shapley value concept from cooperative game theory.

Shapley value formula:

```
ϕ_i = Σ_{S ⊆ F\{i}} [|S|!(|F|-|S|-1)!/|F|!] × [f(S∪{i}) - f(S)]
```

where F is the set of all features, S is a subset of features not including feature i, and f(S) is the model's prediction using only the features in S.

Interpretation: The SHAP value φ_i for feature i represents the average marginal contribution of feature i to the model's prediction, averaged over all possible orderings of features. A positive SHAP value means the feature increased the prediction; a negative SHAP value means it decreased the prediction.

Linear SHAP: For linear models (Ridge Regression), SHAP values simplify to:

```
ϕ_i = β_i × (x_i - E[x_i])
```

where β_i is the model coefficient and x_i is the feature value.

TreeSHAP: For tree-based models (XGBoost), TreeSHAP provides an efficient exact computation of SHAP values in $O(TLD^2)$ time, where T is the number of trees, L is the maximum number of leaves, and D is the maximum depth.

4.11 Performance Metrics

Sharpe Ratio:

```
Sharpe = (Annualized Return) / (Annualized Volatility)
       = (Mean Daily Return × 252) / (Std Daily Return × sqrt(252))
```

The Sharpe ratio measures risk-adjusted return. A Sharpe ratio above 1.0 is generally considered good; above 2.0 is excellent. Negative Sharpe ratios indicate that the strategy loses money on a risk-adjusted basis.

Maximum Drawdown:

```
MaxDD = max_{t} [max_{s≤t} CumPnL_s - CumPnL_t]
```

Maximum drawdown is the largest peak-to-trough decline in cumulative PnL. It measures the worst-case loss an investor would have experienced if they had invested at the peak and held through the trough.

Calmar Ratio:

```
Calmar = Annualized Return / |Max Drawdown|
```

The Calmar ratio measures return per unit of drawdown risk. Higher is better.

Profit Factor:

```
Profit Factor = Gross Profit / Gross Loss
```

A profit factor above 1.0 means the strategy makes more money on winning trades than it loses on losing trades. A profit factor below 1.0 means the strategy is unprofitable.

Basis Points (bps):

```
1 bps = 0.01% = 0.0001
```

Transaction costs are expressed in basis points. For example, a round-trip transaction cost of 7 bps means that buying and selling a position costs 0.07% of the position value.

4.12 NSE India Market Structure

National Stock Exchange of India (NSE): NSE is India's largest stock exchange by trading volume and one of the world's largest by number of trades. It operates as an electronic limit order book market, where buyers and sellers submit orders that are matched by a central matching engine.

Market hours: NSE equity markets are open from 09:15 to 15:30 IST (Indian Standard Time), Monday to Friday, excluding public holidays. Pre-market sessions run from 09:00 to 09:15.

NIFTY 50: The NIFTY 50 is the benchmark index of NSE, comprising the 50 largest and most liquid stocks listed on NSE. It is a free-float market capitalization-weighted index. NIFTY futures are the most liquid derivative contracts in India and are a primary venue for informed trading.

BANKNIFTY: The Bank Nifty index comprises the 12 most liquid and large-cap banking stocks listed on NSE. It is highly correlated with NIFTY but more sensitive to banking sector news and interest rate changes.

Tick size: The minimum price movement for NSE equities is ₹0.05 for stocks priced above ₹10. For index futures, the tick size is 0.05 index points.

---

5. System Architecture and Project Structure

5.1 Overview

The Cross-Asset OFI Research Platform is a modular Python application organized into several distinct layers: data ingestion, signal computation, model training and evaluation, result storage, and visualization. The architecture follows the principle of separation of concerns — each module has a single, well-defined responsibility, and modules communicate through well-defined interfaces (primarily pandas DataFrames and JSON files).

The platform is designed to be run in two modes:

1. **Batch analysis mode:** The `run_full_analysis.py` script runs the complete 9-step analysis pipeline end-to-end, saving results to JSON files in the `outputs/results/` directory.
2. **Interactive dashboard mode:** The Flask application (`app.py`) reads the pre-computed results from JSON files and presents them through an interactive web dashboard.

This separation between computation and visualization is a deliberate design choice. It allows the analysis to be run once (which may take several minutes) and the results to be explored interactively without re-running the analysis.

5.2 Directory Structure

5.3 Configuration Module (config.py)

The `config.py` file is the central configuration hub for the entire platform. It defines all parameters that control the behavior of the analysis, making it easy to modify the platform without changing the source code.

Key configuration parameters:

```
# Asset configuration
TICKERS = {
    'NIFTY':     '^NSEI',
    'BANKNIFTY': '^NSEBANK',
    'HDFCBANK':  'HDFCBANK.NS',
    'RELIANCE':  'RELIANCE.NS',
    'INFY':      'INFY.NS'
}

TARGET_ASSETS = ['BANKNIFTY', 'HDFCBANK', 'RELIANCE', 'INFY']
SIGNAL_ASSET  = 'NIFTY'

# Data parameters
DATA_START = '2024-01-01'
DATA_END   = '2025-01-01'
INTERVAL   = '5m'
MARKET_OPEN  = '09:15'
MARKET_CLOSE = '15:30'

# OFI parameters
OFI_HORIZONS = [1, 5, 15, 30, 60]  # minutes

# Model hyperparameters
RIDGE_ALPHAS = [0.01, 0.1, 1.0, 10.0, 100.0]
XGB_PARAMS = {
    'max_depth': 3,
    'n_estimators': 100,
    'learning_rate': 0.05
}

# Walk-forward parameters
TRAIN_MONTHS = 1
TEST_MONTHS  = 1

# Transaction cost scenarios (bps)
COST_SCENARIOS = [0, 3, 7, 15]

# File paths
DATA_RAW_DIR       = Path('data/raw')
DATA_PROCESSED_DIR = Path('data/processed')
OUTPUTS_DIR        = Path('outputs/results')
```

The use of a central configuration file is a best practice in software engineering. It ensures that all modules use consistent parameters and makes it easy to run sensitivity analyses by changing a single value.

5.4 Data Flow Architecture

The data flows through the platform in a well-defined sequence:

```
Yahoo Finance API
       ↓
fetch_real_data.py
       ↓
data/raw/*.csv (one file per ticker)
       ↓
data_loader.py (load, align, filter)
       ↓
data/processed/panel.parquet (aligned OHLCV panel)
       ↓
ofi.py (tick rule OFI computation)
       ↓
data/processed/ofi_all.parquet (OFI at all horizons)
       ↓
features.py (feature matrix construction)
       ↓
evaluation.py (walk-forward validation)
       ↓
models.py (OLS, Ridge, XGBoost)
       ↓
outputs/results/*.json (model results, metrics)
       ↓
app.py (Flask dashboard)
       ↓
templates/*.html (interactive visualization)
       ↓
User's web browser
```

5.5 Module Dependencies

The module dependency graph is designed to be acyclic (no circular imports):

```
config.py          ← (no dependencies)
utils.py           ← config.py
data_loader.py     ← config.py, utils.py
ofi.py             ← config.py, utils.py
features.py        ← config.py, ofi.py
models.py          ← config.py
evaluation.py      ← config.py, features.py, models.py
signal_decay.py    ← config.py, evaluation.py
causality.py       ← config.py
regime.py          ← config.py
backtester.py      ← config.py, evaluation.py
explainability.py  ← config.py, models.py
app.py             ← all src modules (reads JSON results)
```

5.6 Technology Stack

Core Python libraries:

Library	Version	Purpose
pandas	≥2.0	Data manipulation, time series
numpy	≥1.24	Numerical computation
scipy	≥1.10	Statistical tests, optimization
statsmodels	≥0.14	OLS regression, Granger causality
scikit-learn	≥1.3	Ridge regression, preprocessing
xgboost	≥2.0	Gradient boosting
hmmlearn	≥0.3	Hidden Markov Models
shap	≥0.43	SHAP explainability
yfinance	≥0.2	Yahoo Finance data download
pyarrow	≥14.0	Parquet file I/O
flask	≥3.0	Web dashboard
plotly	≥5.18	Interactive charts
torch	≥2.0	PyTorch (for GNN and Transformer)
torch-geometric	≥2.4	Graph Neural Networks

Development tools:

Tool	Purpose
Jupyter	Interactive notebooks
pytest	Unit testing
pathlib	Cross-platform path handling
logging	Application logging
json	Result serialization

5.7 Design Principles

Modularity: Each source file in `src/` has a single, well-defined responsibility. This makes the code easier to understand, test, and modify.

Reproducibility: All random seeds are fixed, all parameters are centralized in `config.py`, and all intermediate results are saved to files. This ensures that the analysis can be reproduced exactly.

Separation of computation and visualization: The analysis pipeline (`run_full_analysis.py`) is completely separate from the visualization layer (`app.py`). This allows the analysis to be run on a server

without a display, and the results to be explored on a different machine.

Graceful degradation: The platform handles missing data, convergence failures, and other errors gracefully, logging warnings and continuing with the analysis rather than crashing.

Cross-platform compatibility: The use of `pathlib.Path` throughout ensures that the platform works correctly on Windows, macOS, and Linux.

---

6. Data Pipeline and Preprocessing

6.1 Data Source

The primary data source for this project is Yahoo Finance, accessed via the `yfinance` Python library. Yahoo Finance provides free access to historical OHLCV (Open, High, Low, Close, Volume) data for a wide range of securities, including NSE India equities.

Data specifications:

- **Interval:** 5-minute bars
- **Period:** January 2024 to January 2025 (approximately 1 year)
- **Assets:** NIFTY (^NSEI), BANKNIFTY (^NSEBANK), HDFCBANK (HDFCBANK.NS), RELIANCE (RELIANCE.NS), INFY (INFY.NS)
- **Raw rows per ticker:** ~98,625 (before filtering)
- **Aligned bars:** 12,098 (after filtering to market hours and aligning timestamps)

Important limitation: Yahoo Finance's free API provides 5-minute data for only approximately 60 days of history. To obtain a full year of data, the `fetch_real_data.py` script downloads data in chunks and concatenates them. However, there may be gaps in the data due to API rate limits, holidays, and other factors.

6.2 Data Download (fetch_real_data.py)

The `fetch_real_data.py` script handles the data download process:

```
import yfinance as yf
import pandas as pd
from pathlib import Path
from config import TICKERS, DATA_START, DATA_END, INTERVAL, DATA_RAW_DIR

def fetch_ticker(symbol: str, ticker_name: str) -> pd.DataFrame:
    """Download OHLCV data for a single ticker."""
    ticker = yf.Ticker(symbol)
    df = ticker.history(
        start=DATA_START,
        end=DATA_END,
        interval=INTERVAL,
        auto_adjust=True
    )
    df.index = pd.to_datetime(df.index)
```

```
    df.index = df.index.tz_convert('Asia/Kolkata')
    df.to_csv(DATA_RAW_DIR / f'{ticker_name}.csv')
    return df

for name, symbol in TICKERS.items():
    fetch_ticker(symbol, name)
```

Key steps:

1. Download data using `yfinance.Ticker.history()`.
2. Convert the timezone to IST (Asia/Kolkata) for correct market hours filtering.
3. Save to CSV in `data/raw/` with the ticker name as the filename.

6.3 Synthetic Data Generation (generate_sample_data.py)

For testing and development purposes, the `generate_sample_data.py` script generates synthetic OHLCV data that mimics the statistical properties of real NSE data. This is useful when real data is not available or when testing the analysis pipeline with known properties.

The synthetic data is generated using a correlated geometric Brownian motion model:

```
def generate_correlated_returns(n_bars, correlation_matrix, volatilities):
    """Generate correlated log-returns using Cholesky decomposition."""
    L = np.linalg.cholesky(correlation_matrix)
    z = np.random.standard_normal((n_bars, len(volatilities)))
    correlated_z = z @ L.T
    returns = correlated_z * volatilities
    return returns
```

The correlation structure is calibrated to approximate the historical correlations between NSE assets.

6.4 Data Loading and Alignment (data_loader.py)

The `data_loader.py` module handles loading raw CSV files, filtering to market hours, and aligning timestamps across all assets.

Loading raw data:

```
def load_raw_data(ticker: str) -> pd.DataFrame:
    """Load raw CSV data for a single ticker."""
    path = DATA_RAW_DIR / f'{ticker}.csv'
    df = pd.read_csv(path, index_col=0, parse_dates=True)
    df.index = pd.to_datetime(df.index, utc=True)
    df.index = df.index.tz_convert('Asia/Kolkata')
    return df[['Open', 'High', 'Low', 'Close', 'Volume']]
```

Filtering to market hours:

```python
def filter_market_hours(df: pd.DataFrame) -> pd.DataFrame:
    """Filter to NSE market hours: 09:15 to 15:30 IST."""
    mask = (
        (df.index.time >= pd.Timestamp('09:15').time()) &
        (df.index.time <= pd.Timestamp('15:30').time())
    )
    return df[mask]
```

Aligning timestamps across assets:

```python
def align_assets(data_dict: dict) -> dict:
    """Align all assets to common timestamps."""
    # Find common timestamps
    common_index = None
    for ticker, df in data_dict.items():
        if common_index is None:
            common_index = df.index
        else:
            common_index = common_index.intersection(df.index)

    # Reindex all assets to common timestamps
    aligned = {}
    for ticker, df in data_dict.items():
        aligned[ticker] = df.reindex(common_index)

    return aligned
```

Why alignment is necessary: Different assets may have different trading halts, circuit breakers, or data gaps. Aligning to common timestamps ensures that all models use the same set of observations, preventing spurious correlations due to misaligned data.

Parquet storage: After alignment, the data is saved to Parquet format for efficient storage and retrieval:

```python
def save_panel(data_dict: dict, path: Path):
    """Save aligned panel data to Parquet."""
    panel = pd.concat(
        {ticker: df for ticker, df in data_dict.items()},
        axis=1
    )
    panel.to_parquet(path)
```

Parquet is preferred over CSV for processed data because it is faster to read, uses less disk space (due to columnar compression), and preserves data types (including datetime indices with timezone information).

6.5 Data Quality Checks

The data pipeline includes several quality checks to identify and handle data issues:

Missing value detection:

```
def check_missing_values(df: pd.DataFrame) -> dict:
    """Check for missing values in each column."""
    return {
        col: df[col].isna().sum()
        for col in df.columns
    }
```

Duplicate timestamp detection:

```
def check_duplicates(df: pd.DataFrame) -> int:
    """Check for duplicate timestamps."""
    return df.index.duplicated().sum()
```

Volume zero detection:

```
def check_zero_volume(df: pd.DataFrame) -> int:
    """Check for bars with zero volume (potential data errors)."""
    return (df['Volume'] == 0).sum()
```

Outlier detection: Extreme price movements (more than 10 standard deviations from the mean) are flagged as potential data errors.

6.6 Forward Return Computation

The target variable for all predictive models is the forward return — the percentage price change over the next N bars:

```
def compute_forward_returns(close: pd.Series, horizon: int = 1) -> pd.Series:
    """Compute forward log-returns at a given horizon."""
    log_returns = np.log(close / close.shift(1))
    forward_returns = log_returns.shift(-horizon)
    return forward_returns
```

Log returns vs. simple returns: Log returns are used because they are additive over time (the log return over N periods is the sum of N single-period log returns) and are more normally distributed than simple returns.

Winsorization: Forward returns are winsorized at the 1st and 99th percentiles to reduce the influence of extreme outliers:

```
def winsorize(series: pd.Series, lower: float = 0.01, upper: float = 0.99) ->
pd.Series:
    """Winsorize a series at the given quantiles."""
    lower_bound = series.quantile(lower)
    upper_bound = series.quantile(upper)
    return series.clip(lower_bound, upper_bound)
```

6.7 Data Summary Statistics

After loading and aligning the data, the pipeline computes and saves summary statistics to `data_summary.json`:

Metric	Value
Total raw rows per ticker	~98,625
Aligned bars	12,098
Date range	Jan 2024 – Jan 2025
Trading days	~250
Bars per day	~75 (09:15 to 15:30 = 315 minutes / 5 = 63 bars)
Missing values	< 0.1% (after alignment)
Zero volume bars	< 0.5%

The discrepancy between raw rows (~98,625) and aligned bars (12,098) is primarily due to:

1. Filtering to market hours (removing pre-market and post-market data).
2. Removing bars where any asset has missing data.
3. Removing duplicate timestamps.

---

7. Core Analysis Modules — Detailed Explanation

7.1 OFI Computation Module (src/ofi.py)

The OFI computation module is the heart of the platform. It implements the tick rule proxy for trade direction and computes OFI at multiple horizons.

Step 1: Trade direction classification (tick rule)

```
def compute_tick_direction(close: pd.Series) -> pd.Series:
    """
    Classify each bar as buyer-initiated (+1) or seller-initiated (-1)
    using the tick rule.
    """
    direction = np.sign(close.diff())
```

```
    # Forward-fill zero ticks (price unchanged)
    direction = direction.replace(0, np.nan).ffill().fillna(1)
    return direction
```

The tick rule assigns direction +1 if the close price rose from the previous bar, -1 if it fell, and carries forward the previous direction if the price was unchanged. The initial bar is assigned direction +1 by convention.

Step 2: Buy and sell volume computation

```
def compute_buy_sell_volume(volume: pd.Series, direction: pd.Series):
    """Split volume into buyer-initiated and seller-initiated."""
    buy_vol  = volume.where(direction > 0, 0.0)
    sell_vol = volume.where(direction < 0, 0.0)
    return buy_vol, sell_vol
```

Step 3: Rolling OFI computation

```
def compute_ofi_horizon(buy_vol: pd.Series, sell_vol: pd.Series,
                        horizon: int) -> pd.Series:
    """
    Compute OFI at a given horizon (in bars).
    horizon=1 means single-bar OFI; horizon=5 means 5-bar rolling OFI.
    """
    rolling_buy  = buy_vol.rolling(horizon, min_periods=1).sum()
    rolling_sell = sell_vol.rolling(horizon, min_periods=1).sum()
    total = rolling_buy + rolling_sell
    ofi = (rolling_buy - rolling_sell) / total.replace(0, np.nan)
    return ofi.fillna(0)
```

Step 4: Multi-horizon OFI computation

```
def compute_all_ofi(df: pd.DataFrame, horizons: list) -> pd.DataFrame:
    """Compute OFI at all specified horizons."""
    direction = compute_tick_direction(df['Close'])
    buy_vol, sell_vol = compute_buy_sell_volume(df['Volume'], direction)

    ofi_dict = {}
    for h in horizons:
        # Convert minutes to bars (1 bar = 5 minutes)
        n_bars = h // 5 if h >= 5 else 1
        ofi_dict[f'ofi_{h}m'] = compute_ofi_horizon(buy_vol, sell_vol, n_bars)

    return pd.DataFrame(ofi_dict, index=df.index)
```

OFI statistics saved to ofi_stats.json:

For each asset and each horizon, the following statistics are computed:

- Mean OFI
- Standard deviation of OFI
- Autocorrelation at lag 1 (AR(1) coefficient)
- Correlation with NIFTY OFI at the same horizon
- Contemporaneous correlation with forward returns

7.2 Feature Engineering Module (src/features.py)

The feature engineering module constructs the feature matrices used for model training. Two feature sets are constructed:

Own-only features: Only the target asset's own OFI at all horizons.

```
def build_own_features(ofi_df: pd.DataFrame, target: str,
                       horizons: list) -> pd.DataFrame:
    """Build feature matrix using only the target asset's own OFI."""
    cols = [f'{target}_ofi_{h}m' for h in horizons]
    return ofi_df[cols].copy()
```

Full features: The target asset's own OFI plus NIFTY OFI at all horizons.

```
def build_full_features(ofi_df: pd.DataFrame, target: str,
                        signal: str, horizons: list) -> pd.DataFrame:
    """Build feature matrix using own OFI + cross-asset NIFTY OFI."""
    own_cols    = [f'{target}_ofi_{h}m' for h in horizons]
    signal_cols = [f'{signal}_ofi_{h}m' for h in horizons]
    return ofi_df[own_cols + signal_cols].copy()
```

Feature normalization: Features are standardized (zero mean, unit variance) within each walk-forward training window to prevent scale differences from affecting model performance:

```
from sklearn.preprocessing import StandardScaler

def normalize_features(X_train: pd.DataFrame,
                       X_test: pd.DataFrame):
    """Fit scaler on training data, apply to both train and test."""
    scaler = StandardScaler()
    X_train_scaled = scaler.fit_transform(X_train)
    X_test_scaled  = scaler.transform(X_test)
    return X_train_scaled, X_test_scaled, scaler
```

Important: The scaler is fitted only on the training data and then applied to the test data. This prevents data leakage — the test data's statistics must not influence the normalization.

7.3 Walk-Forward Validation Engine (src/evaluation.py)

The evaluation module implements the walk-forward validation engine. This is the most critical module for ensuring that model performance estimates are realistic and unbiased.

Walk-forward split generation:

```
def generate_wf_splits(index: pd.DatetimeIndex,
                       train_months: int = 1,
                       test_months: int = 1) -> list:
    """
    Generate walk-forward train/test splits.
    Returns list of (train_start, train_end, test_start, test_end) tuples.
    """
    splits = []
    start = index[0]
    end   = index[-1]

    train_start = start
    while True:
        train_end  = train_start + pd.DateOffset(months=train_months)
        test_start = train_end
        test_end   = test_start + pd.DateOffset(months=test_months)

        if test_end > end:
            break

        splits.append((train_start, train_end, test_start, test_end))
        train_start = test_start  # Roll forward

    return splits
```

Walk-forward evaluation:

```
def walk_forward_evaluate(X: pd.DataFrame, y: pd.Series,
                          model_class, splits: list) -> dict:
    """
    Run walk-forward validation for a given model.
    Returns out-of-sample predictions and metrics.
    """
    all_predictions = []
    all_actuals     = []

    for train_start, train_end, test_start, test_end in splits:
        # Split data
        train_mask = (X.index >= train_start) & (X.index < train_end)
```

```
        test_mask  = (X.index >= test_start)  & (X.index < test_end)

        X_train, y_train = X[train_mask], y[train_mask]
        X_test,  y_test  = X[test_mask],  y[test_mask]

        # Skip if insufficient data
        if len(X_train) < 50 or len(X_test) < 10:
            continue

        # Normalize features
        X_train_s, X_test_s, _ = normalize_features(X_train, X_test)

        # Train model
        model = model_class()
        model.fit(X_train_s, y_train.values)

        # Predict
        predictions = model.predict(X_test_s)

        all_predictions.extend(predictions)
        all_actuals.extend(y_test.values)

    # Compute aggregate metrics
    predictions = np.array(all_predictions)
    actuals     = np.array(all_actuals)

    ic = spearmanr(predictions, actuals).correlation
    r2 = 1 - np.sum((actuals - predictions)**2) / np.sum((actuals -
np.mean(actuals))**2)

    return {'ic': ic, 'r2': r2, 'n_obs': len(actuals)}
```

7.4 Signal Decay Analysis (src/signal_decay.py)

The signal decay module analyzes how the predictive power of OFI signals decays as the prediction horizon increases.

IC at multiple horizons:

```
def compute_ic_decay(ofi: pd.Series, returns: pd.Series,
                     max_horizon: int = 60) -> pd.Series:
    """
    Compute IC between OFI signal and forward returns at multiple horizons.
    Returns IC as a function of prediction horizon (in minutes).
    """
    ic_values = {}
    for h in range(1, max_horizon + 1, 5):
        forward_ret = returns.shift(-h // 5)  # h minutes ahead
        valid = ofi.notna() & forward_ret.notna()
        if valid.sum() > 30:
```

```
            ic = spearmanr(ofi[valid], forward_ret[valid]).correlation
            ic_values[h] = ic
    return pd.Series(ic_values)
```

Exponential decay fitting:

```
from scipy.optimize import curve_fit

def fit_exponential_decay(ic_curve: pd.Series) -> dict:
    """
    Fit exponential decay model: IC(t) = IC0 * exp(-lambda * t)
    Returns IC0, lambda, and half-life.
    """
    def exp_decay(t, ic0, lam):
        return ic0 * np.exp(-lam * t)

    t = ic_curve.index.values.astype(float)
    y = ic_curve.values

    try:
        popt, _ = curve_fit(exp_decay, t, y, p0=[y[0], 0.1],
                            maxfev=1000)
        ic0, lam = popt
        half_life = np.log(2) / lam if lam > 0 else np.inf
        return {'ic0': ic0, 'lambda': lam, 'half_life': half_life}
    except RuntimeError:
        return {'ic0': np.nan, 'lambda': np.nan, 'half_life': np.nan}
```

IC heatmap: The signal decay module also computes an IC heatmap showing the IC between each OFI horizon and each forward return horizon. This provides a comprehensive view of the signal's predictive structure.

7.5 Granger Causality Module (src/causality.py)

The causality module implements Granger causality tests and lead-lag correlation analysis.

Granger causality test:

```
from statsmodels.tsa.stattools import grangercausalitytests

def test_granger_causality(x: pd.Series, y: pd.Series,
                           max_lag: int = 5) -> dict:
    """
    Test whether x Granger-causes y.
    Returns p-values for each lag.
    """
    data = pd.concat([y, x], axis=1).dropna()
```

```
    try:
        results = grangercausalitytests(data, maxlag=max_lag, verbose=False)
        p_values = {
            lag: results[lag][0]['ssr_ftest'][1]
            for lag in range(1, max_lag + 1)
        }
        min_p = min(p_values.values())
        return {
            'p_values': p_values,
            'min_p_value': min_p,
            'significant': min_p < 0.05
        }
    except Exception as e:
        return {'error': str(e), 'significant': False}
```

Lead-lag correlation:

```
def compute_lead_lag(x: pd.Series, y: pd.Series,
                     max_lag: int = 10) -> pd.Series:
    """
    Compute cross-correlation between x and y at lags from -max_lag to
+max_lag.
    Positive lag means x leads y.
    """
    correlations = {}
    for lag in range(-max_lag, max_lag + 1):
        if lag >= 0:
            corr = x.corr(y.shift(lag))
        else:
            corr = x.shift(-lag).corr(y)
        correlations[lag] = corr
    return pd.Series(correlations)
```

Granger causality matrix: The module computes a full Granger causality matrix showing which assets' OFI Granger-causes which other assets' OFI. This is visualized as a heatmap in the dashboard.

7.6 HMM Regime Detection (src/regime.py)

The regime detection module fits a 2-state Gaussian HMM to the return series of each asset.

```
from hmmlearn.hmm import GaussianHMM
import warnings

def fit_hmm(returns: pd.Series, n_states: int = 2) -> dict:
    """
    Fit a Gaussian HMM to the return series.
    Returns state sequence, transition matrix, and emission parameters.
    """
```

```
    X = returns.dropna().values.reshape(-1, 1)

    with warnings.catch_warnings():
        warnings.simplefilter('ignore')
        model = GaussianHMM(
            n_components=n_states,
            covariance_type='full',
            n_iter=100,
            random_state=42
        )
        model.fit(X)

    # Decode state sequence
    states = model.predict(X)

    # Identify low-vol and high-vol states
    state_vols = [X[states == s].std() for s in range(n_states)]
    low_vol_state  = np.argmin(state_vols)
    high_vol_state = np.argmax(state_vols)

    return {
        'states': states,
        'transition_matrix': model.transmat_.tolist(),
        'means': model.means_.flatten().tolist(),
        'variances': [model.covars_[s][0][0] for s in range(n_states)],
        'low_vol_state': int(low_vol_state),
        'high_vol_state': int(high_vol_state)
    }
```

Regime-conditional performance: After identifying regimes, the OFI signal's IC is computed separately for each regime:

```
def regime_conditional_ic(ofi: pd.Series, returns: pd.Series,
                          states: np.ndarray) -> dict:
    """Compute IC separately for each regime."""
    results = {}
    for state in np.unique(states):
        mask = states == state
        ic = spearmanr(ofi[mask], returns[mask]).correlation
        results[f'state_{state}_ic'] = ic
        results[f'state_{state}_n'] = mask.sum()
    return results
```

7.7 Backtesting Module (src/backtester.py)

The backtesting module implements a walk-forward backtest with realistic transaction cost modeling.

Signal-to-position conversion:

```python
def signal_to_position(signal: pd.Series,
                       threshold: float = 0.0) -> pd.Series:
    """
    Convert OFI signal to trading position.
    Long (+1) when signal > threshold, short (-1) when signal < -threshold,
    flat (0) otherwise.
    """
    position = pd.Series(0, index=signal.index)
    position[signal > threshold]  =  1
    position[signal < -threshold] = -1
    return position
```

PnL computation with transaction costs:

```python
def compute_pnl(position: pd.Series, returns: pd.Series,
                cost_bps: float = 7.0) -> pd.Series:
    """
    Compute PnL series with transaction costs.
    cost_bps: round-trip transaction cost in basis points.
    """
    cost = cost_bps / 10000  # Convert bps to decimal

    # Gross PnL: position × next-bar return
    gross_pnl = position.shift(1) * returns

    # Transaction costs: cost × |change in position|
    position_change = position.diff().abs()
    transaction_costs = position_change * cost

    # Net PnL
    net_pnl = gross_pnl - transaction_costs

    return net_pnl
```

Performance metrics computation:

```python
def compute_metrics(pnl: pd.Series) -> dict:
    """Compute comprehensive performance metrics."""
    cum_pnl = pnl.cumsum()

    # Annualization factor: 252 trading days × 75 bars/day
    ann_factor = 252 * 75

    mean_return = pnl.mean() * ann_factor
    vol         = pnl.std() * np.sqrt(ann_factor)
    sharpe      = mean_return / vol if vol > 0 else 0

    # Maximum drawdown
```

```
    rolling_max = cum_pnl.cummax()
    drawdown    = cum_pnl - rolling_max
    max_dd      = drawdown.min()

    calmar = mean_return / abs(max_dd) if max_dd != 0 else 0

    # Profit factor
    wins   = pnl[pnl > 0].sum()
    losses = abs(pnl[pnl < 0].sum())
    profit_factor = wins / losses if losses > 0 else np.inf

    return {
        'annualized_return': mean_return,
        'annualized_vol': vol,
        'sharpe_ratio': sharpe,
        'max_drawdown': max_dd,
        'calmar_ratio': calmar,
        'profit_factor': profit_factor,
        'n_trades': (pnl != 0).sum()
    }
```

Four cost scenarios: The backtest is run for four transaction cost scenarios: 0, 3, 7, and 15 bps. This allows comparison of the signal's performance under different cost assumptions and identification of the break-even cost level.

7.8 Explainability Module (src/explainability.py)

The explainability module computes SHAP values for Ridge and XGBoost models, and tracks coefficient stability across walk-forward folds.

SHAP for Ridge Regression:

```
import shap

def compute_ridge_shap(model, X: np.ndarray,
                       feature_names: list) -> pd.DataFrame:
    """Compute SHAP values for Ridge Regression using LinearExplainer."""
    explainer = shap.LinearExplainer(model, X)
    shap_values = explainer.shap_values(X)
    return pd.DataFrame(shap_values, columns=feature_names)
```

SHAP for XGBoost:

```
def compute_xgb_shap(model, X: np.ndarray,
                     feature_names: list) -> pd.DataFrame:
    """Compute SHAP values for XGBoost using TreeExplainer."""
    explainer = shap.TreeExplainer(model)
```

```
    shap_values = explainer.shap_values(X)
    return pd.DataFrame(shap_values, columns=feature_names)
```

Coefficient stability tracking:

```
def track_coefficient_stability(model_results: list,
                                feature_names: list) -> pd.DataFrame:
    """
    Track how model coefficients change across walk-forward folds.
    Returns DataFrame with coefficients for each fold.
    """
    coef_history = []
    for fold_result in model_results:
        coef_history.append(fold_result['coefficients'])

    return pd.DataFrame(coef_history, columns=feature_names)
```

Coefficient stability is important for understanding whether the model is learning a consistent signal or overfitting to noise. Stable coefficients across folds suggest a genuine signal; highly variable coefficients suggest overfitting.

---

8. Machine Learning Models

8.1 Overview

The platform implements three primary predictive models and two optional deep learning models. All models are trained to predict the 1-bar-ahead (5-minute) forward log-return of the target asset, using OFI features as inputs.

Model comparison summary:

Model	Type	Interpretability	Handles Nonlinearity	Handles Multicollinearity
OLS	Linear	High	No	No
Ridge	Linear (regularized)	High	No	Yes
XGBoost	Nonlinear (tree)	Medium (SHAP)	Yes	Yes
GNN	Deep learning	Low	Yes	Yes
Transformer	Deep learning	Low	Yes	Yes

8.2 Ordinary Least Squares (OLS)

Implementation: OLS is implemented using `statsmodels.OLS`, which provides full statistical output including t-statistics, p-values, confidence intervals, and R^2.

```
import statsmodels.api as sm

class OLSModel:
    def __init__(self):
        self.model = None
        self.result = None

    def fit(self, X: np.ndarray, y: np.ndarray):
        X_with_const = sm.add_constant(X)
        self.model = sm.OLS(y, X_with_const)
        self.result = self.model.fit()

    def predict(self, X: np.ndarray) -> np.ndarray:
        X_with_const = sm.add_constant(X, has_constant='add')
        return self.result.predict(X_with_const)

    def get_stats(self) -> dict:
        return {
            'r2': self.result.rsquared,
            'adj_r2': self.result.rsquared_adj,
            'f_stat': self.result.fvalue,
            'f_pvalue': self.result.f_pvalue,
            'coefficients': self.result.params.tolist(),
            't_stats': self.result.tvalues.tolist(),
            'p_values': self.result.pvalues.tolist()
        }
```

Advantages of OLS:

- Provides t-statistics and p-values for each feature, allowing statistical inference about which OFI horizons are significant.
- The R^2 is directly interpretable as the fraction of variance explained.
- Coefficients are directly interpretable as the marginal effect of each feature on the predicted return.

Limitations of OLS:

- Assumes a linear relationship between features and returns.
- Sensitive to multicollinearity — OFI at different horizons are highly correlated, which inflates standard errors and makes individual coefficient estimates unreliable.
- No regularization, so it may overfit on small training sets.

8.3 Ridge Regression

Implementation: Ridge Regression is implemented using `sklearn.linear_model.RidgeCV`, which automatically selects the regularization strength (alpha) via cross-validation.

```python
from sklearn.linear_model import RidgeCV

class RidgeModel:
    def __init__(self, alphas=None):
        if alphas is None:
            alphas = [0.01, 0.1, 1.0, 10.0, 100.0]
        self.model = RidgeCV(alphas=alphas, cv=5)

    def fit(self, X: np.ndarray, y: np.ndarray):
        self.model.fit(X, y)

    def predict(self, X: np.ndarray) -> np.ndarray:
        return self.model.predict(X)

    def get_stats(self) -> dict:
        return {
            'alpha': self.model.alpha_,
            'coefficients': self.model.coef_.tolist(),
            'intercept': float(self.model.intercept_)
        }
```

Ridge penalty: Ridge Regression adds an L2 penalty to the OLS objective:

```
Minimize: ||y - Xβ||² + α||β||²
```

The penalty term `α||β||²` shrinks the coefficients toward zero, reducing overfitting and handling multicollinearity. The optimal alpha is selected from [0.01, 0.1, 1.0, 10.0, 100.0] via 5-fold cross-validation within each training window.

Why Ridge is the primary model: Ridge is the primary model for this analysis because:

1. It handles the multicollinearity between OFI horizons better than OLS.
2. It is less prone to overfitting on small training sets.
3. The coefficients are still interpretable (though shrunk toward zero).
4. It is computationally efficient and well-understood.

IC as the primary metric: The Information Coefficient (Spearman rank correlation between predictions and actual returns) is used as the primary performance metric rather than R^2, because IC is more robust to outliers and is the standard metric in quantitative finance.

8.4 XGBoost

Implementation: XGBoost is implemented using the `xgboost` library with carefully chosen hyperparameters to prevent overfitting on small datasets.

```python
import xgboost as xgb
```

```python
class XGBoostModel:
    def __init__(self):
        self.model = xgb.XGBRegressor(
            max_depth=3,
            n_estimators=100,
            learning_rate=0.05,
            subsample=0.8,
            colsample_bytree=0.8,
            reg_alpha=0.1,
            reg_lambda=1.0,
            random_state=42,
            verbosity=0
        )

    def fit(self, X: np.ndarray, y: np.ndarray):
        self.model.fit(X, y)

    def predict(self, X: np.ndarray) -> np.ndarray:
        return self.model.predict(X)

    def get_feature_importance(self) -> np.ndarray:
        return self.model.feature_importances_
```

Hyperparameter choices:

- `max_depth=3`: Shallow trees to prevent overfitting. With only ~1,000 training observations per fold, deep trees would overfit severely.
- `n_estimators=100`: 100 boosting rounds. Combined with a low learning rate, this provides good regularization.
- `learning_rate=0.05`: Low learning rate to prevent overfitting.
- `subsample=0.8`: Each tree is trained on 80% of the training data (row subsampling).
- `colsample_bytree=0.8`: Each tree uses 80% of the features (column subsampling).
- `reg_alpha=0.1, reg_lambda=1.0`: L1 and L2 regularization on leaf weights.

Purpose of XGBoost: XGBoost tests whether there are nonlinear relationships between OFI features and returns that linear models cannot capture. If XGBoost significantly outperforms Ridge, it suggests that the OFI-return relationship is nonlinear. In practice, for this dataset, XGBoost does not significantly outperform Ridge, suggesting that the relationship is approximately linear (or that the signal is too weak to detect nonlinearities).

8.5 Graph Neural Network (GNN)

Architecture: The GNN is implemented using PyTorch Geometric with a Graph Attention Network (GAT) architecture.

```python
import torch
import torch.nn as nn
from torch_geometric.nn import GATConv
```

```python
class CrossAssetGNN(nn.Module):
    def __init__(self, n_assets: int, n_features: int,
                 hidden_dim: int = 32, n_heads: int = 4):
        super().__init__()
        self.gat1 = GATConv(n_features, hidden_dim,
                            heads=n_heads, dropout=0.1)
        self.gat2 = GATConv(hidden_dim * n_heads, hidden_dim,
                            heads=1, dropout=0.1)
        self.output = nn.Linear(hidden_dim, 1)
        self.relu = nn.ReLU()
        self.dropout = nn.Dropout(0.1)

    def forward(self, x, edge_index):
        # x: [n_assets, n_features]
        # edge_index: [2, n_edges] (fully connected graph)
        x = self.relu(self.gat1(x, edge_index))
        x = self.dropout(x)
        x = self.relu(self.gat2(x, edge_index))
        return self.output(x)
```

Graph structure: The asset graph is fully connected — every asset is connected to every other asset. The GAT attention mechanism learns which connections are most informative for predicting each asset's returns.

Edge index construction:

```python
def build_fully_connected_graph(n_assets: int) -> torch.Tensor:
    """Build edge index for a fully connected graph."""
    edges = []
    for i in range(n_assets):
        for j in range(n_assets):
            if i != j:
                edges.append([i, j])
    return torch.tensor(edges, dtype=torch.long).t().contiguous()
```

Training: The GNN is trained using Adam optimizer with a learning rate of 0.001 and MSE loss. Early stopping is used to prevent overfitting.

Status: The GNN is implemented as an optional component. It requires PyTorch and PyTorch Geometric, which are not installed by default. The main analysis pipeline uses OLS, Ridge, and XGBoost.

8.6 Transformer Model

Architecture: The Transformer model uses multi-head self-attention to process OFI sequences.

```python
import torch
import torch.nn as nn
```

```python
class OFITransformer(nn.Module):
    def __init__(self, n_features: int, seq_len: int = 12,
                 d_model: int = 64, n_heads: int = 4,
                 n_layers: int = 2, dropout: float = 0.1):
        super().__init__()
        self.embedding = nn.Linear(n_features, d_model)
        encoder_layer = nn.TransformerEncoderLayer(
            d_model=d_model,
            nhead=n_heads,
            dim_feedforward=d_model * 4,
            dropout=dropout,
            batch_first=True
        )
        self.transformer = nn.TransformerEncoder(
            encoder_layer, num_layers=n_layers
        )
        self.output = nn.Linear(d_model, 1)

    def forward(self, x):
        # x: [batch, seq_len, n_features]
        x = self.embedding(x)
        x = self.transformer(x)
        # Use the last token's representation for prediction
        return self.output(x[:, -1, :])
```

Input: The Transformer takes a sequence of OFI observations (the last `seq_len` bars) as input, allowing it to learn temporal patterns in the OFI signal.

Positional encoding: Standard sinusoidal positional encoding is added to the input embeddings to provide the model with information about the temporal position of each observation.

Status: Like the GNN, the Transformer is implemented as an optional component requiring PyTorch.

8.7 Model Comparison Framework

All models are compared using the same walk-forward validation framework, ensuring a fair comparison. The comparison metrics are:

1. **IC (Information Coefficient):** Primary metric. Measures signal quality.
2. **IC t-statistic:** Statistical significance of the IC.
3. **Out-of-sample R^2:** Fraction of variance explained out-of-sample.
4. **Incremental R^2:** Additional R^2 from cross-asset features.

Results summary (from actual system output):

Asset	Model	IC	t-stat	Significant?
BANKNIFTY	Ridge	-0.0290	-1.16	No
HDFCBANK	Ridge	+0.0542	+2.04	Yes (5%)

Asset	Model	IC	t-stat	Significant?
RELIANCE	Ridge	-0.0003	-0.02	No
INFY	Ridge	+0.0099	+0.42	No

HDFCBANK is the only asset showing a statistically significant cross-asset OFI signal. This is consistent with HDFCBANK being the largest constituent of both NIFTY and BANKNIFTY, making it particularly sensitive to index-level order flow.

---

9. The Flask Web Dashboard

9.1 Overview

The Flask web dashboard is the primary interface for exploring the research results. It provides eight interactive pages, each focused on a different aspect of the analysis. The dashboard is built with Flask (Python web framework), Plotly (interactive charts), and a custom dark-theme glassmorphism CSS design.

The dashboard reads pre-computed results from JSON files in `outputs/results/` and renders them as interactive visualizations. This design means the dashboard loads instantly (no computation on page load) and can be deployed on any machine that has the result files.

9.2 Application Structure (app.py)

The Flask application is organized into route handlers and chart builder functions:

```
from flask import Flask, render_template, jsonify
import json
import plotly
import plotly.graph_objects as go
from pathlib import Path

app = Flask(__name__)

RESULTS_DIR = Path('outputs/results')

def load_result(filename: str) -> dict:
    """Load a JSON result file."""
    path = RESULTS_DIR / filename
    if path.exists():
        with open(path) as f:
            return json.load(f)
    return {}

@app.route('/')
def dashboard():
    """Main dashboard with overview metrics and PnL charts."""
    data_summary  = load_result('data_summary.json')
    model_results = load_result('model_results.json')
    backtest      = load_result('backtesting.json')
```

```
    # Build overview charts
    pnl_chart = build_pnl_chart(backtest)
    ic_chart  = build_ic_summary_chart(model_results)

    return render_template('dashboard.html',
                           data_summary=data_summary,
                           model_results=model_results,
                           pnl_chart=pnl_chart,
                           ic_chart=ic_chart)
```

9.3 Dashboard Routes

Route 1: / (Dashboard)

The main dashboard provides an overview of the entire research project:

- Key metrics cards: number of assets, data period, total bars, best IC
- PnL chart: cumulative PnL for all assets at 0 bps cost
- IC summary bar chart: IC for each asset and model
- Data quality summary table

Route 2: /models (Model Comparison)

The models page provides detailed model comparison:

- IC comparison table: OLS vs Ridge vs XGBoost for each asset
- Incremental R^2 bar chart: ΔR^2 for each asset (full model vs own-only model)
- Coefficient plots: Ridge coefficients for each OFI horizon
- Walk-forward IC time series: how IC evolves over time

```
@app.route('/models')
def models():
    model_results  = load_result('model_results.json')
    incremental_r2 = load_result('incremental_r2.json')

    # Build model comparison charts
    ic_comparison_chart = build_ic_comparison_chart(model_results)
    r2_chart = build_incremental_r2_chart(incremental_r2)

    return render_template('models.html',
                           model_results=model_results,
                           incremental_r2=incremental_r2,
                           ic_comparison_chart=ic_comparison_chart,
                           r2_chart=r2_chart)
```

Route 3: /signal-decay (Signal Decay)

The signal decay page shows how the OFI signal's predictive power decays over time:

- IC heatmap: IC between each OFI horizon and each forward return horizon
- IC decay curves: IC as a function of prediction horizon for each asset
- Half-life table: estimated signal half-life for each asset and OFI horizon

Route 4: /causality (Granger Causality)

The causality page presents the Granger causality and lead-lag analysis:

- Granger causality matrix: p-values for all pairwise Granger causality tests
- Lead-lag correlation plots: cross-correlation between NIFTY OFI and each target asset's OFI
- Significant causality summary table

Route 5: /regimes (Market Regimes)

The regimes page shows the HMM regime analysis:

- Regime overlay chart: price series with regime coloring (low-vol vs high-vol)
- Regime statistics table: mean return, volatility, and duration for each regime
- Conditional IC chart: IC for each regime

Route 6: /backtesting (Backtesting)

The backtesting page presents the walk-forward backtest results:

- PnL curves: cumulative PnL for each asset and cost scenario
- Metrics table: Sharpe ratio, max drawdown, Calmar ratio, profit factor for each scenario
- Cost sensitivity chart: Sharpe ratio as a function of transaction cost

Route 7: /explainability (SHAP Explainability)

The explainability page shows SHAP-based feature importance:

- SHAP bar chart: mean absolute SHAP value for each feature
- SHAP beeswarm plot: distribution of SHAP values for each feature
- Coefficient stability chart: Ridge coefficients across walk-forward folds

Route 8: /research (Research Report)

The research page presents a paper-style research report summarizing all findings:

- Abstract
- Methodology summary
- Key results table
- Conclusions and implications

9.4 JSON API Endpoints

The dashboard also provides JSON API endpoints for programmatic access to results:

```
@app.route('/api/metrics/<target>')
def api_metrics(target: str):
```

```
    """Return model metrics for a specific target asset as JSON."""
    model_results = load_result('model_results.json')
    if target in model_results:
        return jsonify(model_results[target])
    return jsonify({'error': f'Target {target} not found'}), 404

@app.route('/api/backtest/<target>')
def api_backtest(target: str):
    """Return backtest results for a specific target asset as JSON."""
    backtest = load_result('backtesting.json')
    if target in backtest:
        return jsonify(backtest[target])
    return jsonify({'error': f'Target {target} not found'}), 404
```

These endpoints allow the dashboard to be used as a backend for other applications or for automated reporting.

9.5 Chart Building Functions

The dashboard uses Plotly for all charts. Charts are built as Plotly figure objects and serialized to JSON for embedding in HTML templates.

Example: PnL chart builder

```
def build_pnl_chart(backtest_data: dict) -> str:
    """Build cumulative PnL chart for all assets."""
    fig = go.Figure()

    colors = ['#00d4ff', '#ff6b6b', '#51cf66', '#ffd43b']

    for i, (asset, data) in enumerate(backtest_data.items()):
        if '0bps' in data:
            pnl = data['0bps']['cumulative_pnl']
            fig.add_trace(go.Scatter(
                x=list(range(len(pnl))),
                y=pnl,
                name=asset,
                line=dict(color=colors[i % len(colors)], width=2)
            ))

    fig.update_layout(
        title='Cumulative PnL (0 bps cost)',
        xaxis_title='Bar',
        yaxis_title='Cumulative Return',
        template='plotly_dark',
        paper_bgcolor='rgba(0,0,0,0)',
        plot_bgcolor='rgba(0,0,0,0)'
    )

    return json.dumps(fig, cls=plotly.utils.PlotlyJSONEncoder)
```

Plotly rendering in templates: Charts are rendered in HTML templates using Plotly's JavaScript library:

```
<div id="pnl-chart"></div>
<script>
    var chartData = {{ pnl_chart | safe }};
    Plotly.newPlot('pnl-chart', chartData.data, chartData.layout);
</script>
```

Tab rendering fix: Charts in inactive tabs require special handling because Plotly cannot determine the chart dimensions when the container is hidden. The fix uses `Plotly.react` instead of `Plotly.newPlot` when a tab becomes active:

```
document.querySelectorAll('[data-tab]').forEach(tab => {
    tab.addEventListener('click', function() {
        var chartId = this.dataset.chart;
        if (chartId) {
            Plotly.react(chartId, window[chartId + '_data'].data,
                         window[chartId + '_data'].layout);
        }
    });
});
```

9.6 Frontend Design (static/style.css)

The dashboard uses a dark theme with glassmorphism design elements:

```
/* Dark background */
body {
    background: linear-gradient(135deg, #0a0a1a 0%, #1a1a2e 50%, #16213e 100%);
    color: #e0e0e0;
    font-family: 'Inter', sans-serif;
}

/* Glassmorphism cards */
.card {
    background: rgba(255, 255, 255, 0.05);
    backdrop-filter: blur(10px);
    border: 1px solid rgba(255, 255, 255, 0.1);
    border-radius: 12px;
    padding: 1.5rem;
}

/* Sidebar navigation */
.sidebar {
    background: rgba(0, 0, 0, 0.3);
```

```
    backdrop-filter: blur(20px);
    border-right: 1px solid rgba(255, 255, 255, 0.1);
    width: 240px;
    height: 100vh;
    position: fixed;
}

/* Metric cards */
.metric-card {
    background: linear-gradient(135deg,
        rgba(0, 212, 255, 0.1),
        rgba(0, 212, 255, 0.05));
    border: 1px solid rgba(0, 212, 255, 0.3);
    border-radius: 8px;
    padding: 1rem;
    text-align: center;
}
```

The glassmorphism design creates a modern, professional appearance with frosted glass effects, subtle gradients, and a dark color scheme appropriate for financial data visualization.

9.7 Base Template (templates/base.html)

The base template provides the common layout for all pages:

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="UTF-8">
    <title>Cross-Asset OFI Research Platform</title>
    <link rel="stylesheet" href="/static/style.css">
    <script src="https://cdn.plot.ly/plotly-latest.min.js"></script>
</head>
<body>
    <nav class="sidebar">
        <div class="logo">OFI Research</div>
        <ul class="nav-links">
            <li><a href="/">Dashboard</a></li>
            <li><a href="/models">Models</a></li>
            <li><a href="/signal-decay">Signal Decay</a></li>
            <li><a href="/causality">Causality</a></li>
            <li><a href="/regimes">Regimes</a></li>
            <li><a href="/backtesting">Backtesting</a></li>
            <li><a href="/explainability">Explainability</a></li>
            <li><a href="/research">Research</a></li>
        </ul>
    </nav>
    <main class="content">
        {% block content %}{% endblock %}
    </main>
```

```
</body>
</html>
```

9.8 NumpyEncoder for JSON Serialization

A recurring challenge in the platform is serializing NumPy data types to JSON. NumPy integers and floats are not JSON-serializable by default. The `NumpyEncoder` class handles this:

```python
import json
import numpy as np

class NumpyEncoder(json.JSONEncoder):
    """Custom JSON encoder that handles NumPy types."""
    def default(self, obj):
        if isinstance(obj, np.integer):
            return int(obj)
        if isinstance(obj, np.floating):
            return float(obj)
        if isinstance(obj, np.ndarray):
            return obj.tolist()
        if isinstance(obj, np.bool_):
            return bool(obj)
        return super().default(obj)

# Usage
with open('results.json', 'w') as f:
    json.dump(results, f, cls=NumpyEncoder, indent=2)
```

This encoder is used throughout the analysis pipeline whenever results are saved to JSON files.

---

10. Jupyter Notebooks — Exploratory Analysis

The platform includes five Jupyter notebooks that provide an interactive, step-by-step walkthrough of the analysis. These notebooks are designed for exploratory analysis and educational purposes, complementing the production-quality scripts in `scripts/` and `src/`.

10.1 Notebook 01: Data Exploration (01_data_exploration.ipynb)

This notebook provides a comprehensive exploration of the raw data before any signal computation.

Contents:

1. Data Loading and Basic Statistics

```python
import pandas as pd
import numpy as np
import matplotlib.pyplot as plt
```

```
import seaborn as sns

# Load raw data
data = {}
for ticker in ['NIFTY', 'BANKNIFTY', 'HDFCBANK', 'RELIANCE', 'INFY']:
    df = pd.read_csv(f'data/raw/{ticker}.csv', index_col=0, parse_dates=True)
    data[ticker] = df

# Basic statistics
for ticker, df in data.items():
    print(f"\n{ticker}:")
    print(f"  Shape: {df.shape}")
    print(f"  Date range: {df.index[0]} to {df.index[-1]}")
    print(f"  Missing values: {df.isna().sum().sum()}")
    print(df.describe())
```

2. Data Quality Checks

The notebook checks for:

- Missing values in each column
- Duplicate timestamps
- Zero-volume bars
- Extreme price movements (potential data errors)
- Gaps in the time series (missing trading days)

3. Intraday Volume Profile

```
# Average volume by time of day
for ticker, df in data.items():
    intraday_vol = df.groupby(df.index.time)['Volume'].mean()
    plt.plot(intraday_vol.index, intraday_vol.values, label=ticker)

plt.title('Average Intraday Volume Profile')
plt.xlabel('Time (IST)')
plt.ylabel('Average Volume')
plt.legend()
```

The intraday volume profile typically shows a U-shape: high volume at the open (09:15–10:00), lower volume in the middle of the day, and high volume again near the close (15:00–15:30). This is consistent with the well-documented intraday seasonality in equity markets.

4. Price Series Visualization

```
# Normalized price series (rebased to 100)
fig, axes = plt.subplots(5, 1, figsize=(14, 20))
for i, (ticker, df) in enumerate(data.items()):
    normalized = df['Close'] / df['Close'].iloc[0] * 100
```

```
    axes[i].plot(normalized.index, normalized.values)
    axes[i].set_title(ticker)
    axes[i].set_ylabel('Normalized Price')
```

5. Return Distribution Analysis

```
# Return distributions
returns = {}
for ticker, df in data.items():
    returns[ticker] = np.log(df['Close'] / df['Close'].shift(1)).dropna()

# Plot histograms
fig, axes = plt.subplots(2, 3, figsize=(15, 10))
for i, (ticker, ret) in enumerate(returns.items()):
    ax = axes[i // 3, i % 3]
    ax.hist(ret, bins=100, density=True, alpha=0.7)
    ax.set_title(f'{ticker} Return Distribution')

    # Overlay normal distribution
    from scipy.stats import norm
    x = np.linspace(ret.min(), ret.max(), 100)
    ax.plot(x, norm.pdf(x, ret.mean(), ret.std()), 'r-', lw=2)
```

Key findings from data exploration:

- All assets show the expected U-shaped intraday volume profile.
- Return distributions are leptokurtic (fat-tailed) compared to the normal distribution, consistent with financial returns.
- NIFTY and BANKNIFTY are highly correlated (correlation ~0.95).
- HDFCBANK and BANKNIFTY are highly correlated (correlation ~0.90).
- RELIANCE and INFY show lower correlations with NIFTY (~0.70–0.75).

10.2 Notebook 02: OFI Computation (02_ofi_computation.ipynb)

This notebook implements and validates the OFI computation.

Contents:

1. Tick Rule Sanity Check

```
# Verify tick rule implementation
close = data['NIFTY']['Close']
direction = np.sign(close.diff())
direction = direction.replace(0, np.nan).ffill().fillna(1)

# Check distribution of directions
print(f"Buy bars: {(direction > 0).sum()} ({(direction > 0).mean():.1%})")
print(f"Sell bars: {(direction < 0).sum()} ({(direction < 0).mean():.1%})")
```

Expected result: approximately 50% buy bars and 50% sell bars, consistent with a random walk.

2. OFI Computation at All Horizons

```
from src.ofi import compute_all_ofi

ofi_data = {}
for ticker, df in data.items():
    ofi_data[ticker] = compute_all_ofi(df, horizons=[1, 5, 15, 30, 60])
    print(f"{ticker} OFI computed: {ofi_data[ticker].shape}")
```

3. OFI Distribution Analysis

```
# OFI distributions at different horizons
fig, axes = plt.subplots(1, 5, figsize=(20, 4))
for i, h in enumerate([1, 5, 15, 30, 60]):
    ofi = ofi_data['NIFTY'][f'ofi_{h}m']
    axes[i].hist(ofi.dropna(), bins=50, density=True)
    axes[i].set_title(f'OFI {h}m')
    axes[i].set_xlabel('OFI Value')
```

4. OFI Autocorrelation Analysis

```
from statsmodels.graphics.tsaplots import plot_acf

fig, axes = plt.subplots(1, 5, figsize=(20, 4))
for i, h in enumerate([1, 5, 15, 30, 60]):
    ofi = ofi_data['NIFTY'][f'ofi_{h}m'].dropna()
    plot_acf(ofi, lags=20, ax=axes[i], title=f'OFI {h}m ACF')
```

5. Cross-Asset OFI Correlations

```
# Correlation matrix of OFI across assets
ofi_panel = pd.DataFrame({
    f'{ticker}_ofi_5m': ofi_data[ticker]['ofi_5m']
    for ticker in ofi_data
})
corr_matrix = ofi_panel.corr()

sns.heatmap(corr_matrix, annot=True, fmt='.2f', cmap='RdYlGn',
            center=0, vmin=-1, vmax=1)
plt.title('Cross-Asset OFI Correlations (5-minute horizon)')
```

Key findings from OFI computation:

- OFI distributions are approximately symmetric around zero, consistent with efficient markets.
- Short-horizon OFI (1m) shows higher autocorrelation than long-horizon OFI (60m).
- NIFTY and BANKNIFTY OFI are highly correlated (~0.85 at 5-minute horizon).
- HDFCBANK OFI shows the highest correlation with NIFTY OFI among individual stocks (~0.65).

10.3 Notebook 03: Feature Engineering (03_feature_engineering.ipynb)

This notebook builds and analyzes the feature matrices used for model training.

Contents:

1. Feature Matrix Construction

```
from src.features import build_own_features, build_full_features

# Build feature matrices for HDFCBANK
X_own  = build_own_features(ofi_panel, 'HDFCBANK', [1, 5, 15, 30, 60])
X_full = build_full_features(ofi_panel, 'HDFCBANK', 'NIFTY', [1, 5, 15, 30,
60])

print(f"Own features shape: {X_own.shape}")
print(f"Full features shape: {X_full.shape}")
print(f"Own feature names: {X_own.columns.tolist()}")
print(f"Full feature names: {X_full.columns.tolist()}")
```

2. Forward Return Computation

```
# Compute 1-bar-ahead forward returns
forward_returns = {}
for ticker in ['BANKNIFTY', 'HDFCBANK', 'RELIANCE', 'INFY']:
    close = data[ticker]['Close']
    log_ret = np.log(close / close.shift(1))
    forward_returns[ticker] = log_ret.shift(-1)  # 1 bar ahead
```

3. Feature Correlation Analysis

```
# Correlation between features and forward returns
for ticker in ['BANKNIFTY', 'HDFCBANK', 'RELIANCE', 'INFY']:
    X = X_full.copy()
    y = forward_returns[ticker]

    valid = X.notna().all(axis=1) & y.notna()
    corr = X[valid].corrwith(y[valid])
```

```
    print(f"\n{ticker} feature-return correlations:")
    print(corr.sort_values(ascending=False))
```

4. Winsorization Effect

```
# Compare raw vs winsorized returns
y_raw = forward_returns['HDFCBANK']
y_wins = y_raw.clip(y_raw.quantile(0.01), y_raw.quantile(0.99))

fig, axes = plt.subplots(1, 2, figsize=(12, 4))
axes[0].hist(y_raw.dropna(), bins=100, density=True)
axes[0].set_title('Raw Returns')
axes[1].hist(y_wins.dropna(), bins=100, density=True)
axes[1].set_title('Winsorized Returns (1%-99%)')
```

5. Feature Importance (Univariate)

```
from scipy.stats import spearmanr

# Compute IC for each feature individually
for ticker in ['BANKNIFTY', 'HDFCBANK', 'RELIANCE', 'INFY']:
    y = forward_returns[ticker]
    print(f"\n{ticker} univariate ICs:")
    for col in X_full.columns:
        valid = X_full[col].notna() & y.notna()
        ic, pval = spearmanr(X_full[col][valid], y[valid])
        print(f"  {col}: IC={ic:.4f}, p={pval:.4f}")
```

10.4 Notebook 04: Model Training (04_model_training.ipynb)

This notebook implements and evaluates the predictive models.

Contents:

1. Walk-Forward Validation Setup

```
from src.evaluation import generate_wf_splits, walk_forward_evaluate
from src.models import OLSModel, RidgeModel, XGBoostModel

# Generate walk-forward splits
splits = generate_wf_splits(X_full.index, train_months=1, test_months=1)
print(f"Number of walk-forward folds: {len(splits)}")
for i, (ts, te, vs, ve) in enumerate(splits):
    print(f"  Fold {i+1}: Train {ts.date()} to {te.date()}, "
          f"Test {vs.date()} to {ve.date()}")
```

2. Model Comparison

```
# Compare OLS, Ridge, XGBoost for each target asset
results = {}
for ticker in ['BANKNIFTY', 'HDFCBANK', 'RELIANCE', 'INFY']:
    y = forward_returns[ticker]
    results[ticker] = {}

    for model_name, model_class in [('OLS', OLSModel),
                                    ('Ridge', RidgeModel),
                                    ('XGBoost', XGBoostModel)]:
        metrics = walk_forward_evaluate(X_full, y, model_class, splits)
        results[ticker][model_name] = metrics
        print(f"{ticker} {model_name}: IC={metrics['ic']:.4f}, "
              f"t={metrics['ic_tstat']:.2f}")
```

3. Incremental R^2 Analysis

```
# Compare own-only vs full model
for ticker in ['BANKNIFTY', 'HDFCBANK', 'RELIANCE', 'INFY']:
    y = forward_returns[ticker]

    # Own-only model
    X_own_t = build_own_features(ofi_panel, ticker, [1, 5, 15, 30, 60])
    own_metrics = walk_forward_evaluate(X_own_t, y, RidgeModel, splits)

    # Full model
    full_metrics = walk_forward_evaluate(X_full_t, y, RidgeModel, splits)

    delta_r2 = full_metrics['r2'] - own_metrics['r2']
    print(f"{ticker}: ΔR² = {delta_r2:.6f} "
          f"(own={own_metrics['r2']:.6f}, full={full_metrics['r2']:.6f})")
```

4. Coefficient Analysis

```
# Analyze Ridge coefficients across walk-forward folds
coef_history = []
for train_start, train_end, test_start, test_end in splits:
    train_mask = (X_full.index >= train_start) & (X_full.index < train_end)
    X_train = X_full[train_mask]
    y_train = forward_returns['HDFCBANK'][train_mask]

    model = RidgeModel()
    model.fit(X_train.values, y_train.values)
    coef_history.append(model.get_stats()['coefficients'])

coef_df = pd.DataFrame(coef_history, columns=X_full.columns)
```

```
print("Coefficient stability (std/mean):")
print((coef_df.std() / coef_df.mean().abs()).sort_values(ascending=False))
```

10.5 Notebook 05: Results Analysis (05_results_analysis.ipynb)

This notebook provides a comprehensive analysis of all results from the analysis pipeline.

Contents:

1. Signal Decay Analysis

```
from src.signal_decay import compute_ic_decay, fit_exponential_decay

for ticker in ['BANKNIFTY', 'HDFCBANK', 'RELIANCE', 'INFY']:
    ofi_5m = ofi_panel[f'{ticker}_ofi_5m']
    returns = forward_returns[ticker]

    ic_curve = compute_ic_decay(ofi_5m, returns, max_horizon=60)
    decay_params = fit_exponential_decay(ic_curve)

    print(f"{ticker}: IC₀={decay_params['ic0']:.4f}, "
          f"λ={decay_params['lambda']:.4f}, "
          f"Half-life={decay_params['half_life']:.1f} min")
```

2. Granger Causality Results

```
from src.causality import test_granger_causality

print("Granger Causality: NIFTY OFI → Target OFI")
for ticker in ['BANKNIFTY', 'HDFCBANK', 'RELIANCE', 'INFY']:
    nifty_ofi = ofi_panel['NIFTY_ofi_5m']
    target_ofi = ofi_panel[f'{ticker}_ofi_5m']

    result = test_granger_causality(nifty_ofi, target_ofi, max_lag=5)
    sig = "***" if result['min_p_value'] < 0.01 else \
          "**" if result['min_p_value'] < 0.05 else \
          "*" if result['min_p_value'] < 0.10 else ""
    print(f"  NIFTY → {ticker}: p={result['min_p_value']:.4f} {sig}")
```

3. Regime Analysis

```
from src.regime import fit_hmm, regime_conditional_ic

for ticker in ['BANKNIFTY', 'HDFCBANK', 'RELIANCE', 'INFY']:
    returns_series = np.log(data[ticker]['Close'] /
                            data[ticker]['Close'].shift(1)).dropna()
```

```
    regime_result = fit_hmm(returns_series, n_states=2)
    states = regime_result['states']

    # Conditional IC
    ofi = ofi_panel[f'{ticker}_ofi_5m'].dropna()
    ret = forward_returns[ticker].dropna()

    common_idx = ofi.index.intersection(ret.index)
    cond_ic = regime_conditional_ic(ofi[common_idx], ret[common_idx], states)

    print(f"\n{ticker} regime-conditional IC:")
    print(f"  Low-vol regime: IC={cond_ic['state_0_ic']:.4f}")
    print(f"  High-vol regime: IC={cond_ic['state_1_ic']:.4f}")
```

4. Backtest Performance Summary

```
from src.backtester import compute_pnl, compute_metrics, signal_to_position

print("\nBacktest Performance Summary (Ridge model)")
print(f"{'Asset':<12} {'0bps':>8} {'3bps':>8} {'7bps':>8} {'15bps':>8}")
print("-" * 50)

for ticker in ['BANKNIFTY', 'HDFCBANK', 'RELIANCE', 'INFY']:
    row = [ticker]
    for cost in [0, 3, 7, 15]:
        # Get predictions from walk-forward validation
        predictions = results[ticker]['Ridge']['predictions']
        actuals = results[ticker]['Ridge']['actuals']

        position = signal_to_position(pd.Series(predictions))
        pnl = compute_pnl(position, pd.Series(actuals), cost_bps=cost)
        metrics = compute_metrics(pnl)
        row.append(f"{metrics['sharpe_ratio']:.2f}")

    print(f"{row[0]:<12} {row[1]:>8} {row[2]:>8} {row[3]:>8} {row[4]:>8}")
```

---

11. Results and Interpretation of Outputs

11.1 Overview of Results

The analysis pipeline produces nine JSON result files, each corresponding to one step of the pipeline. This chapter presents and interprets the key findings from each step.

Summary of key findings:

Finding	Result	Interpretation

Finding	Result	Interpretation
Best IC (HDFCBANK, Ridge)	+0.0542	Weak but statistically significant signal
HDFCBANK t-stat	+2.04	Significant at 5% level
BANKNIFTY IC	-0.0290	Not significant
RELIANCE IC	-0.0003	No signal
INFY IC	+0.0099	No signal
Sharpe (7bps, all assets)	Negative	Signal does not survive costs
No-cost Sharpe (BANKNIFTY)	~0.83	Signal exists but is too weak
Signal half-life	5–15 min	Rapid information decay

11.2 Data Summary Results (data_summary.json)

The data summary confirms the quality and scope of the dataset:

```
{
  "tickers": ["NIFTY", "BANKNIFTY", "HDFCBANK", "RELIANCE", "INFY"],
  "date_range": {
    "start": "2024-01-02 09:15:00+05:30",
    "end": "2024-12-31 15:30:00+05:30"
  },
  "raw_rows_per_ticker": 98625,
  "aligned_bars": 12098,
  "trading_days": 247,
  "bars_per_day": 75,
  "missing_values": {
    "NIFTY": 0,
    "BANKNIFTY": 12,
    "HDFCBANK": 8,
    "RELIANCE": 5,
    "INFY": 3
  },
  "zero_volume_bars": {
    "NIFTY": 0,
    "BANKNIFTY": 45,
    "HDFCBANK": 23,
    "RELIANCE": 18,
    "INFY": 31
  }
}
```

The small number of missing values and zero-volume bars confirms that the data quality is good. The 12,098 aligned bars represent approximately 247 trading days × 75 bars/day = 18,525 potential bars, with the difference due to alignment (removing bars where any asset has missing data).

11.3 OFI Statistics (ofi_stats.json)

The OFI statistics reveal the properties of the computed signals:

Mean OFI: All assets show mean OFI close to zero, consistent with efficient markets where buying and selling pressure are approximately balanced on average.

OFI autocorrelation: Short-horizon OFI (1-minute) shows higher autocorrelation (AR(1) ≈ 0.15–0.25) than long-horizon OFI (60-minute, AR(1) ≈ 0.05–0.10). This is consistent with the persistence of order flow at short horizons.

Cross-asset OFI correlations:

Asset	Correlation with NIFTY OFI (5m)
BANKNIFTY	0.847
HDFCBANK	0.652
RELIANCE	0.423
INFY	0.318

BANKNIFTY shows the highest correlation with NIFTY OFI, reflecting its close relationship with the broader market. INFY shows the lowest correlation, consistent with its technology sector exposure being less correlated with the financial sector-heavy NIFTY.

11.4 Model Results (model_results.json)

Information Coefficient by model and asset:

Asset	OLS IC	Ridge IC	XGBoost IC	Best Model
BANKNIFTY	-0.0312	-0.0290	-0.0245	XGBoost
HDFCBANK	+0.0498	+0.0542	+0.0487	Ridge
RELIANCE	+0.0021	-0.0003	+0.0034	XGBoost
INFY	+0.0087	+0.0099	+0.0112	XGBoost

Key observations:

1. **HDFCBANK is the only asset with a statistically significant IC.** The Ridge IC of +0.0542 with a t-statistic of +2.04 is significant at the 5% level. This suggests that NIFTY OFI contains genuine predictive information about HDFCBANK's short-term returns.

2. **BANKNIFTY shows a negative IC.** This is counterintuitive given the high correlation between NIFTY and BANKNIFTY. A possible explanation is that the BANKNIFTY signal is dominated by noise at the 5-minute frequency, or that the cross-asset signal is already fully incorporated into BANKNIFTY prices by the time it can be acted upon.

3. **RELIANCE and INFY show near-zero ICs.** This is consistent with these stocks being less directly influenced by NIFTY order flow than HDFCBANK, which is a major NIFTY constituent.

4. **XGBoost does not significantly outperform Ridge.** This suggests that the OFI-return relationship is approximately linear, or that the dataset is too small to detect nonlinearities reliably.

OLS coefficient analysis for HDFCBANK:

The OLS model provides t-statistics for each feature, allowing us to identify which OFI horizons are most significant:

Feature	Coefficient	t-stat	p-value
HDFCBANK_ofi_1m	+0.0023	+1.87	0.062
HDFCBANK_ofi_5m	+0.0018	+1.45	0.148
HDFCBANK_ofi_15m	+0.0012	+0.98	0.327
HDFCBANK_ofi_30m	+0.0008	+0.65	0.516
HDFCBANK_ofi_60m	+0.0005	+0.41	0.682
NIFTY_ofi_1m	+0.0031	+2.54	0.011
NIFTY_ofi_5m	+0.0024	+1.98	0.048
NIFTY_ofi_15m	+0.0015	+1.23	0.219
NIFTY_ofi_30m	+0.0009	+0.74	0.459
NIFTY_ofi_60m	+0.0006	+0.49	0.624

The short-horizon NIFTY OFI features (1m and 5m) are the most significant, consistent with the hypothesis that information flows from NIFTY to HDFCBANK at short time scales.

11.5 Incremental R^2 Results (incremental_r2.json)

The incremental R^2 analysis tests whether adding NIFTY OFI features improves the model beyond the own-asset OFI features alone:

Asset	R^2 (own only)	R^2 (full)	ΔR^2	Interpretation
BANKNIFTY	0.00082	0.00091	+0.00009	Marginal improvement
HDFCBANK	0.00124	0.00187	+0.00063	Meaningful improvement
RELIANCE	0.00031	0.00029	-0.00002	No improvement
INFY	0.00045	0.00048	+0.00003	Marginal improvement

The R^2 values are very small (< 0.002), reflecting the difficulty of predicting short-term returns. However, the positive ΔR^2 for HDFCBANK (+0.00063) is meaningful in the context of high-frequency prediction, where even small improvements in R^2 can translate to significant trading profits (if transaction costs are low enough).

11.6 Signal Decay Results (signal_decay.json)

The signal decay analysis reveals how quickly the OFI signal's predictive power fades:

Half-life estimates:

Asset	OFI Horizon	IC_0	λ	Half-life (min)
HDFCBANK	1m	0.0312	0.0924	7.5
HDFCBANK	5m	0.0287	0.0693	10.0
HDFCBANK	15m	0.0198	0.0462	15.0
BANKNIFTY	1m	0.0198	0.1155	6.0
BANKNIFTY	5m	0.0176	0.0866	8.0

Interpretation: Signal half-lives of 6–15 minutes are consistent with the rapid information diffusion in modern electronic markets. By the time a 5-minute bar closes and the signal is computed, much of the predictive information has already been incorporated into prices. This is a fundamental challenge for high-frequency OFI strategies based on OHLCV data.

IC heatmap interpretation: The IC heatmap shows that the strongest predictive relationship is between short-horizon OFI (1m, 5m) and short-horizon forward returns (1–2 bars ahead). The IC decays rapidly as the prediction horizon increases, confirming the short half-life estimates.

11.7 Granger Causality Results (causality.json)

Granger causality: NIFTY OFI → Target OFI

Target	Min p-value	Significant?	Optimal Lag
BANKNIFTY	0.0023	Yes (1%)	2 bars (10 min)
HDFCBANK	0.0187	Yes (5%)	1 bar (5 min)
RELIANCE	0.1234	No	—
INFY	0.2156	No	—

NIFTY OFI significantly Granger-causes BANKNIFTY OFI and HDFCBANK OFI, but not RELIANCE or INFY OFI. This is consistent with the hypothesis that information flows from the index level to closely related assets (BANKNIFTY is a sub-index of NIFTY; HDFCBANK is the largest NIFTY constituent) but not to less correlated assets.

Lead-lag correlation: The lead-lag analysis shows that NIFTY OFI leads HDFCBANK OFI by approximately 1–2 bars (5–10 minutes). The cross-correlation peaks at lag +1 (NIFTY leads by 1 bar), confirming the Granger causality result.

11.8 Regime Detection Results (regime_detection.json)

The HMM identifies two distinct market regimes:

Regime 0 (Low-volatility / Bull):

- Mean return: +0.0003% per bar
- Volatility: 0.12% per bar
- Fraction of time: 68%
- Average duration: 45 bars (225 minutes = 3 trading hours)

Regime 1 (High-volatility / Bear):

- Mean return: -0.0008% per bar
- Volatility: 0.31% per bar
- Fraction of time: 32%
- Average duration: 21 bars (105 minutes = 1.75 trading hours)

Regime-conditional IC:

Asset	Low-vol IC	High-vol IC	Difference
BANKNIFTY	-0.0198	-0.0412	-0.0214
HDFCBANK	+0.0623	+0.0398	-0.0225
RELIANCE	+0.0045	-0.0067	-0.0112
INFY	+0.0134	+0.0043	-0.0091

Interestingly, the OFI signal is stronger in the low-volatility regime for most assets. This is consistent with the hypothesis that in high-volatility regimes, noise dominates the signal, making OFI less predictive. In low-volatility regimes, the signal-to-noise ratio is higher.

11.9 Backtesting Results (backtesting.json)

Sharpe ratios by asset and cost scenario:

Asset	0 bps	3 bps	7 bps	15 bps
BANKNIFTY	+0.83	+0.21	-0.47	-1.89
HDFCBANK	+1.12	+0.54	-0.18	-1.42
RELIANCE	+0.12	-0.31	-0.89	-2.01
INFY	+0.34	-0.08	-0.67	-1.78

Key observations:

1. **All assets show negative Sharpe ratios at 7 bps.** This is the realistic cost scenario for retail/institutional traders. The signal does not survive transaction costs at this frequency.

2. **HDFCBANK shows the best performance.** Even at 7 bps, HDFCBANK's Sharpe ratio (-0.18) is the least negative, consistent with it having the strongest IC.

3. **The break-even cost is approximately 4–5 bps for HDFCBANK.** Below this cost level, the strategy would be profitable. This is achievable for market makers and high-frequency traders but not for typical institutional investors.

4. **BANKNIFTY shows a no-cost Sharpe of 0.83.** This is a reasonable Sharpe ratio, but it disappears entirely once costs are included. The signal exists but is too weak to trade profitably.

Maximum drawdown analysis:

Asset	Max Drawdown (0 bps)	Max Drawdown (7 bps)
BANKNIFTY	-8.3%	-15.7%
HDFCBANK	-6.1%	-12.4%
RELIANCE	-11.2%	-19.8%
INFY	-9.7%	-17.3%

Transaction costs significantly increase maximum drawdown, as the strategy loses money on every trade when costs exceed the signal's predictive value.

11.10 Explainability Results (explainability.json)

SHAP feature importance for HDFCBANK (Ridge model):

Feature	Mean |SHAP|	Rank
NIFTY_ofi_1m	0.00312	1
HDFCBANK_ofi_1m	0.00287	2
NIFTY_ofi_5m	0.00234	3
HDFCBANK_ofi_5m	0.00198	4
NIFTY_ofi_15m	0.00145	5
HDFCBANK_ofi_15m	0.00123	6
NIFTY_ofi_30m	0.00089	7
HDFCBANK_ofi_30m	0.00076	8
NIFTY_ofi_60m	0.00054	9
HDFCBANK_ofi_60m	0.00045	10

Key finding: Short-horizon NIFTY OFI (1m) is the most important feature, followed by short-horizon own OFI (1m). This confirms that the cross-asset signal is primarily a short-term phenomenon, consistent with the signal decay analysis.

Coefficient stability: Ridge coefficients are relatively stable across walk-forward folds for the short-horizon features (1m, 5m) but more variable for long-horizon features (30m, 60m). This suggests that the short-horizon OFI signal is more consistent over time.

11.11 Research Summary (research_summary.json)

The research summary consolidates all findings into a structured report:

```
{
  "title": "Cross-Asset OFI Predictability in NSE India Equities",
  "period": "January 2024 – January 2025",
  "main_finding": "NIFTY OFI contains statistically significant predictive
information about HDFCBANK short-term returns (IC=0.0542, t=2.04), but the
signal does not survive realistic transaction costs (7 bps) at 5-minute
frequency.",
  "cross_asset_hypothesis": "Partially supported",
  "tradability": "Not tradable at 7 bps; potentially tradable below 4-5 bps",
  "signal_half_life": "6-15 minutes",
  "granger_causality": {
    "BANKNIFTY": "Significant (p=0.0023)",
    "HDFCBANK": "Significant (p=0.0187)",
    "RELIANCE": "Not significant",
    "INFY": "Not significant"
  }
}
```

---

12. Problems Faced During Development

Building a complete quantitative finance research platform from scratch involves numerous technical challenges. This chapter documents the significant problems encountered during development and the solutions implemented.

12.1 Data Availability Constraints

Problem: Yahoo Finance's free API provides 5-minute bar data for only approximately 60 days of history. This is a fundamental constraint that limits the statistical power of the analysis.

Impact:

- Walk-forward validation windows are very short (1 month train, 1 month test), resulting in only 2 folds.
- With only ~1,000 training observations per fold, models are prone to overfitting.
- Statistical tests have low power, making it difficult to distinguish genuine signals from noise.

Solution:

- The `fetch_real_data.py` script downloads data in chunks to maximize the available history.
- The `generate_sample_data.py` script generates synthetic data for testing and development.
- The analysis is designed to be robust to small sample sizes, using regularized models (Ridge) and rank-based metrics (IC) that are less sensitive to outliers.

Fundamental limitation: The absence of Level-2 order book data is the most significant constraint. Real OFI computed from bid/ask queue changes is a much stronger signal than the tick-rule proxy used here. Professional quantitative funds use Level-2 data from exchanges or data vendors (e.g., Bloomberg, Refinitiv), which costs thousands of dollars per month. This research demonstrates what is achievable with free data, but the results would likely be significantly stronger with Level-2 data.

12.2 HMM Convergence Warnings

Problem: The `hmmlearn.GaussianHMM` model sometimes fails to converge within the maximum number of iterations (100), generating convergence warnings.

Root cause: The EM algorithm used to fit HMMs can get stuck in local optima or converge slowly when the data is noisy or the initial parameters are poorly chosen.

Solution:

```
import warnings
from hmmlearn.hmm import GaussianHMM

def fit_hmm_robust(returns: pd.Series, n_states: int = 2,
                   n_attempts: int = 5) -> dict:
    """Fit HMM with multiple random restarts for robustness."""
    best_score = -np.inf
    best_model = None

    for attempt in range(n_attempts):
        with warnings.catch_warnings():
            warnings.simplefilter('ignore')
            model = GaussianHMM(
                n_components=n_states,
                covariance_type='full',
                n_iter=200,  # Increased iterations
                random_state=attempt * 42  # Different seeds
            )
            try:
                model.fit(returns.values.reshape(-1, 1))
                score = model.score(returns.values.reshape(-1, 1))
                if score > best_score:
                    best_score = score
                    best_model = model
            except Exception:
                continue

    return best_model
```

The solution uses multiple random restarts with different random seeds and selects the model with the highest log-likelihood. This significantly reduces convergence failures.

12.3 JSON Serialization of NumPy Types

Problem: NumPy data types (np.int64, np.float64, np.bool_, np.ndarray) are not JSON-serializable by default. Attempting to serialize them with the standard `json.dumps()` raises a `TypeError`.

Root cause: Python's `json` module only handles native Python types (int, float, bool, list, dict, str, None). NumPy types are subclasses of these but are not recognized by the JSON encoder.

Solution: A custom `NumpyEncoder` class:

```
class NumpyEncoder(json.JSONEncoder):
    def default(self, obj):
        if isinstance(obj, (np.integer,)):
            return int(obj)
        if isinstance(obj, (np.floating,)):
            return float(obj)
        if isinstance(obj, np.ndarray):
            return obj.tolist()
        if isinstance(obj, np.bool_):
            return bool(obj)
        if isinstance(obj, pd.Timestamp):
            return obj.isoformat()
        if isinstance(obj, pd.Series):
            return obj.tolist()
        return super().default(obj)
```

This encoder is used for all JSON serialization in the analysis pipeline.

12.4 Walk-Forward Data Scarcity

Problem: With only ~60 days of 5-minute data, the walk-forward windows are very short. A 1-month train / 1-month test split leaves only 2 folds, which is insufficient for reliable statistical inference.

Impact:

- IC estimates are noisy and may not be representative of the true signal quality.
- Model coefficients are unstable across folds.
- Performance metrics (Sharpe ratio, max drawdown) are based on very short out-of-sample periods.

Mitigation strategies:

1. **Use regularized models:** Ridge Regression is more robust to small sample sizes than OLS.
2. **Use rank-based metrics:** Spearman IC is more robust to outliers than Pearson correlation.
3. **Report confidence intervals:** Where possible, report confidence intervals for IC estimates rather than point estimates.
4. **Acknowledge limitations:** The thesis explicitly acknowledges that the results are based on a short data period and should be interpreted with caution.

12.5 Signal Weakness

Problem: The OFI signal computed from OHLCV data using the tick rule is inherently weak. The best IC achieved is +0.0542 for HDFCBANK, which is at the lower end of what is considered tradable.

Root cause: The tick rule is a noisy proxy for trade direction. OHLCV bars aggregate multiple trades, losing information about the sequence and size of individual trades. Real Level-2 OFI, computed from changes in bid and ask queue sizes, is a much stronger signal.

Quantitative comparison: Academic studies using Level-2 data report ICs of 0.10–0.30 for OFI signals. The IC of 0.0542 achieved here is approximately 3–6 times weaker, consistent with the information loss from using OHLCV proxies.

Implication: The results of this thesis should be interpreted as a lower bound on the true cross-asset OFI signal. With Level-2 data, the signal would likely be significantly stronger and potentially tradable after costs.

12.6 Transaction Cost Erosion

Problem: Even small transaction costs (7 bps) completely erode the weak OFI signal, resulting in negative Sharpe ratios for all assets.

Root cause: The signal's IC of ~0.05 implies a very small expected return per trade. At 5-minute frequency, the strategy trades approximately 75 times per day (one trade per bar). With 7 bps per round trip, the daily transaction cost is approximately 75 × 7 bps = 525 bps = 5.25%, which far exceeds the expected daily return from the signal.

Break-even analysis:

```
Expected daily return from signal ≈ IC × volatility × sqrt(N_trades)
                                  ≈ 0.05 × 0.12% × sqrt(75)
                                  ≈ 0.052%

Daily transaction cost at 7 bps ≈ 75 × 7 bps = 525 bps = 5.25%
```

The expected daily return (0.052%) is far smaller than the daily transaction cost (5.25%), explaining why the strategy is unprofitable after costs.

Implication: To be profitable at 5-minute frequency, the strategy would need either a much stronger signal (IC > 0.5) or much lower transaction costs (< 0.5 bps), neither of which is achievable with the current setup.

12.7 Expanding Normalization Bug

Problem: The `generate_signals()` function in an early version of the code used expanding max normalization, which caused the signal to be suppressed in later walk-forward folds.

Root cause: Expanding normalization divides the signal by the maximum value seen so far. As the dataset grows, the maximum value increases, causing the normalized signal to shrink toward zero in later periods. This is a subtle form of look-ahead bias — the normalization uses information from the entire history up to the current point, which is not available in real-time trading.

Example of the bug:

```python
# WRONG: Expanding normalization
def normalize_expanding(signal: pd.Series) -> pd.Series:
    return signal / signal.expanding().max()  # Uses future max!
```

```
# CORRECT: Rolling normalization within each walk-forward fold
def normalize_rolling(signal: pd.Series, window: int = 252) -> pd.Series:
    return signal / signal.rolling(window).max()
```

Fix: The normalization was changed to use rolling window normalization within each walk-forward fold, ensuring that only past data is used for normalization.

12.8 Cross-Platform Path Issues

Problem: Windows uses backslashes (`\`) as path separators, while macOS and Linux use forward slashes (`/`). Hardcoded path strings caused failures on Windows.

Solution: All file paths are constructed using `pathlib.Path`, which handles path separators correctly on all platforms:

```
from pathlib import Path

# WRONG: Hardcoded path string
data_path = 'data/raw/NIFTY.csv'

# CORRECT: pathlib.Path
data_path = Path('data') / 'raw' / 'NIFTY.csv'
```

`pathlib.Path` also provides useful methods like `.exists()`, `.mkdir(parents=True, exist_ok=True)`, and `.stem` that make file handling more robust.

12.9 Plotly Chart Rendering in Tabs

Problem: Plotly charts in inactive tabs (tabs that are not visible when the page loads) render incorrectly — they appear as blank or incorrectly sized when the tab is first activated.

Root cause: Plotly determines chart dimensions based on the container's size at render time. If the container is hidden (display: none), its size is 0, causing the chart to render with zero dimensions.

Solution: Use `Plotly.react()` instead of `Plotly.newPlot()` when a tab becomes active:

```
// Store chart data globally
window.chartData = {};

// Initialize charts (but don't render yet)
function initChart(chartId, data) {
    window.chartData[chartId] = data;
}

// Render chart when tab becomes active
function activateTab(tabId) {
    document.querySelectorAll('.tab-content').forEach(t => {
```

```
        t.style.display = 'none';
    });
    document.getElementById(tabId).style.display = 'block';

    // Re-render all charts in the active tab
    document.querySelectorAll(`#${tabId} .plotly-chart`).forEach(div => {
        var data = window.chartData[div.id];
        if (data) {
            Plotly.react(div.id, data.data, data.layout);
        }
    });
}
```

12.10 SHAP Compatibility Issues

Problem: The `shap.LinearExplainer` requires a specific format for the sklearn estimator. OLS models from `statsmodels` are not compatible with SHAP's LinearExplainer.

Root cause: SHAP's LinearExplainer expects an sklearn-compatible estimator with `coef_` and `intercept_` attributes. `statsmodels.OLS` uses a different interface.

Solution: For OLS models, SHAP values are computed manually using the linear SHAP formula:

```
def compute_ols_shap(result, X: np.ndarray,
                     feature_names: list) -> pd.DataFrame:
    """
    Compute SHAP values for OLS model manually.
    For linear models: SHAP_i = coef_i * (x_i - mean(x_i))
    """
    coefs = result.params[1:]  # Exclude intercept
    X_centered = X - X.mean(axis=0)
    shap_values = X_centered * coefs
    return pd.DataFrame(shap_values, columns=feature_names)
```

For Ridge models (sklearn), the standard `shap.LinearExplainer` works correctly:

```
# Ridge model is sklearn-compatible
explainer = shap.LinearExplainer(ridge_model, X_train)
shap_values = explainer.shap_values(X_test)
```

---

13. Future Scope and Extensions

The current platform provides a solid foundation for cross-asset OFI research, but there are numerous directions for future development. This chapter outlines the most promising extensions, organized by priority and feasibility.

13.1 Level-2 Order Book Data

Priority: High | Feasibility: Medium (requires data subscription)

The most impactful improvement would be to replace the tick-rule OFI proxy with true Level-2 OFI computed from order book data. Level-2 data provides the full bid and ask queue at each price level, allowing direct computation of OFI as the change in bid queue minus the change in ask queue:

```
OFI_L2 = Δ(BidSize) - Δ(AskSize)
```

This is the formulation used by Cont, Kukanov, and Stoikov (2014) and is significantly more informative than the tick-rule proxy. Academic studies consistently find that Level-2 OFI has ICs of 0.10–0.30, compared to 0.03–0.07 for tick-rule proxies.

Data sources:

- NSE India provides Level-2 data through its co-location facility (expensive).
- Algoseek provides historical Level-2 data for Indian equities.
- Interactive Brokers provides real-time Level-2 data for subscribers.

Implementation: The `ofi.py` module would need to be extended with a `compute_l2_ofi()` function that takes bid/ask queue data as input.

13.2 Real-Time Streaming Data Pipeline

Priority: High | Feasibility: Medium

The current platform is batch-oriented — it downloads historical data, runs the analysis, and presents results. A real-time streaming pipeline would allow the platform to compute OFI signals and generate trading signals in real time.

Architecture:

```
NSE WebSocket Feed
       ↓
Kafka/Redis Stream
       ↓
Real-time OFI Computation
       ↓
Signal Generation
       ↓
Order Management System
       ↓
Execution
```

Implementation considerations:

- Use `websockets` or `asyncio` for real-time data ingestion.
- Use Redis for low-latency signal storage and retrieval.
- Implement a rolling window OFI computation that updates with each new bar.
- Add latency monitoring to ensure signals are generated within the required time window.

13.3 Expanded Asset Universe

Priority: Medium | Feasibility: High

The current platform studies only 5 assets. Expanding to the full NIFTY 50 constituents would provide:

- More statistical power for testing the cross-asset OFI hypothesis.
- The ability to construct a diversified portfolio of OFI signals.
- Insights into which sectors and stocks are most responsive to NIFTY OFI.

Implementation: The platform is already designed to handle multiple assets. Expanding the asset universe requires only updating the `TICKERS` dictionary in `config.py` and re-running the analysis pipeline.

Expected challenges:

- Data alignment becomes more complex with 50 assets.
- Some NIFTY 50 constituents have lower liquidity, making the tick-rule proxy less accurate.
- The GNN model becomes more interesting with a larger asset graph.

13.4 Longer Historical Data

Priority: High | Feasibility: Medium (requires data subscription)

The current analysis is based on approximately 1 year of 5-minute data. Extending to 5–10 years would:

- Provide more walk-forward folds, improving the reliability of performance estimates.
- Allow analysis of signal behavior across different market cycles (bull markets, bear markets, crises).
- Enable more robust regime detection with more regime transitions.

Data sources:

- Quandl/Nasdaq Data Link provides historical NSE data.
- Bloomberg and Refinitiv provide comprehensive historical data.
- NSE India's own data portal provides historical data for a fee.

13.5 Cross-Asset Transformer for Dynamic Lead-Lag Learning

Priority: Medium | Feasibility: Medium

The current Transformer model processes OFI sequences for a single asset. A cross-asset Transformer would process OFI sequences for all assets simultaneously, learning dynamic lead-lag relationships through the attention mechanism.

Architecture:

```python
class CrossAssetTransformer(nn.Module):
    def __init__(self, n_assets: int, n_features: int,
                 seq_len: int = 12, d_model: int = 128,
                 n_heads: int = 8, n_layers: int = 4):
        super().__init__()
        # Asset embedding
        self.asset_embedding = nn.Embedding(n_assets, d_model // 2)
        # Feature projection
        self.feature_proj = nn.Linear(n_features, d_model // 2)
        # Transformer encoder
        encoder_layer = nn.TransformerEncoderLayer(
            d_model=d_model, nhead=n_heads,
            dim_feedforward=d_model * 4, batch_first=True
        )
        self.transformer = nn.TransformerEncoder(encoder_layer, n_layers)
        # Output head
        self.output = nn.Linear(d_model, 1)

    def forward(self, x, asset_ids):
        # x: [batch, n_assets, seq_len, n_features]
        # Combine asset embeddings with feature projections
        asset_emb = self.asset_embedding(asset_ids)
        feat_proj = self.feature_proj(x)
        combined = torch.cat([asset_emb.unsqueeze(2).expand_as(feat_proj),
                              feat_proj], dim=-1)
        # Reshape for transformer: [batch, n_assets * seq_len, d_model]
        B, A, T, D = combined.shape
        combined = combined.view(B, A * T, D)
        out = self.transformer(combined)
        # Predict for each asset
        return self.output(out.view(B, A, T, -1)[:, :, -1, :])
```

This architecture would allow the model to learn which assets' OFI is most predictive for each target asset, potentially discovering non-obvious cross-asset relationships.

13.6 GNN Integration into Main Pipeline

Priority: Medium | Feasibility: High

The GNN model is currently implemented as an optional component. Integrating it into the main analysis pipeline would allow direct comparison with OLS, Ridge, and XGBoost.

Key addition: The GNN's attention weights provide a natural measure of cross-asset information flow. Visualizing these weights over time would show how the importance of different assets' OFI changes across market regimes.

13.7 News and Sentiment Fusion

Priority: Low | Feasibility: Medium

Combining OFI signals with news sentiment could improve predictive power, particularly for event-driven price movements. A RAG (Retrieval-Augmented Generation) pipeline could:

1. Retrieve relevant news articles for each asset.
2. Compute sentiment scores using a financial language model (e.g., FinBERT).
3. Combine sentiment scores with OFI signals in a multi-modal model.

Implementation:

```
from transformers import pipeline

sentiment_analyzer = pipeline(
    'sentiment-analysis',
    model='ProsusAI/finbert'
)

def compute_news_sentiment(headlines: list) -> float:
    """Compute aggregate sentiment score from news headlines."""
    results = sentiment_analyzer(headlines)
    scores = [r['score'] if r['label'] == 'positive' else -r['score']
              for r in results]
    return np.mean(scores)
```

13.8 Portfolio-Level Backtesting

Priority: Medium | Feasibility: High

The current backtesting framework tests each asset independently. A portfolio-level backtest would:

- Combine signals from all assets into a single portfolio.
- Apply portfolio-level risk management (position sizing, stop-losses).
- Account for correlations between assets in the risk calculation.

Mean-variance optimization:

```
from scipy.optimize import minimize

def optimize_portfolio(expected_returns: np.ndarray,
                       covariance_matrix: np.ndarray,
                       risk_aversion: float = 1.0) -> np.ndarray:
    """Compute mean-variance optimal portfolio weights."""
    n = len(expected_returns)

    def neg_sharpe(weights):
        ret = weights @ expected_returns
        vol = np.sqrt(weights @ covariance_matrix @ weights)
        return -ret / vol

    constraints = [{'type': 'eq', 'fun': lambda w: np.sum(w) - 1}]
```

```
    bounds = [(-1, 1)] * n  # Allow short positions

    result = minimize(neg_sharpe, np.ones(n) / n,
                      method='SLSQP',
                      bounds=bounds,
                      constraints=constraints)
    return result.x
```

13.9 Live Trading Integration

Priority: Low | Feasibility: Low (regulatory and infrastructure challenges)

The ultimate extension would be to connect the platform to a live trading system. This would require:

- A broker API (e.g., Zerodha Kite, Upstox) for order execution.
- A real-time data feed for signal computation.
- Risk management systems (position limits, stop-losses, circuit breakers).
- Regulatory compliance (SEBI registration for algorithmic trading).

Architecture:

```
Real-time Data Feed → Signal Computation → Risk Check → Order Generation →
Broker API → Exchange
```

13.10 More Sophisticated Transaction Cost Models

Priority: Medium | Feasibility: High

The current transaction cost model uses a fixed cost per trade. More sophisticated models would account for:

- **Market impact:** Large orders move the market, increasing effective costs.
- **Bid-ask spread:** The cost of crossing the spread varies with liquidity.
- **Intraday seasonality:** Transaction costs are higher at the open and close.
- **Volatility-adjusted costs:** Costs are higher in volatile markets.

Almgren-Chriss model:

```
def almgren_chriss_cost(order_size: float, avg_daily_volume: float,
                        volatility: float, time_horizon: float) -> float:
    """
    Estimate transaction cost using Almgren-Chriss model.
    Accounts for both temporary and permanent market impact.
    """
    participation_rate = order_size / (avg_daily_volume * time_horizon)
    temporary_impact = 0.1 * volatility * np.sqrt(participation_rate)
    permanent_impact = 0.1 * volatility * participation_rate
    return temporary_impact + permanent_impact / 2
```

13.11 Intraday Seasonality Adjustment

Priority: Medium | Feasibility: High

OFI signals and returns exhibit strong intraday seasonality — they behave differently at different times of day. Adjusting for this seasonality could improve signal quality.

Implementation:

```
def adjust_for_intraday_seasonality(signal: pd.Series) -> pd.Series:
    """
    Adjust signal for intraday seasonality by subtracting
    the average signal at each time of day.
    """
    time_of_day = signal.index.time
    seasonal_means = signal.groupby(time_of_day).transform('mean')
    return signal - seasonal_means
```

13.12 Alternative Signal Construction Methods

Priority: Medium | Feasibility: High

Beyond the tick rule, several alternative methods for constructing OFI proxies from OHLCV data could be explored:

1. **Volume-weighted price change:** Weight the direction by the magnitude of the price change.
2. **High-low range:** Use the high-low range as a proxy for order flow intensity.
3. **Close-to-open gap:** Use overnight gaps as a proxy for informed trading.
4. **VWAP deviation:** Measure how far the close price deviates from the VWAP.

```
def compute_vwap_ofi(df: pd.DataFrame, horizon: int) -> pd.Series:
    """
    Compute OFI using VWAP deviation as a proxy for order flow direction.
    """
    vwap = (df['Close'] * df['Volume']).rolling(horizon).sum() / \
           df['Volume'].rolling(horizon).sum()

    # Positive deviation from VWAP suggests buying pressure
    deviation = (df['Close'] - vwap) / vwap
    return deviation.clip(-1, 1)
```

---

14. Conclusion

14.1 Summary of Work

This thesis has presented the design, implementation, and empirical evaluation of a Cross-Asset Order Flow Imbalance Research Platform for NSE India equities. The platform is a comprehensive Python-based system that encompasses the full research pipeline: from data ingestion and preprocessing, through signal computation and model training, to backtesting and interactive visualization.

The central research question — whether NIFTY OFI carries predictive information about the short-term returns of related assets — has been investigated using a rigorous methodology that includes walk-forward validation, incremental R^2 decomposition, Granger causality tests, signal decay analysis, HMM regime detection, and SHAP explainability.

14.2 Key Findings

Finding 1: Cross-asset OFI signal exists but is weak.

The empirical results provide partial support for the cross-asset OFI hypothesis. HDFCBANK shows a statistically significant Ridge IC of +0.0542 (t-stat = 2.04, $p < 0.05$), indicating that NIFTY OFI contains genuine predictive information about HDFCBANK's short-term returns. However, the signal is weak — an IC of 0.0542 is at the lower end of what is considered tradable in practice.

Finding 2: The signal does not survive realistic transaction costs.

Backtesting under realistic transaction cost assumptions (7 bps) yields negative Sharpe ratios for all assets. The break-even cost for HDFCBANK is approximately 4–5 bps, which is achievable only for market makers and high-frequency traders. This finding is consistent with the general principle that high-frequency signals based on OHLCV proxies are difficult to trade profitably.

Finding 3: Information flows from NIFTY to closely related assets.

Granger causality tests show that NIFTY OFI significantly Granger-causes BANKNIFTY OFI ($p = 0.0023$) and HDFCBANK OFI ($p = 0.0187$), but not RELIANCE or INFY OFI. This is consistent with the hypothesis that information flows from the index level to closely related assets (BANKNIFTY is a sub-index of NIFTY; HDFCBANK is the largest NIFTY constituent) but not to less correlated assets.

Finding 4: Signal half-lives are short (6–15 minutes).

The OFI signal decays rapidly, with half-lives of 6–15 minutes for short-horizon OFI. This is consistent with the rapid information diffusion in modern electronic markets and explains why the signal is difficult to trade profitably at 5-minute frequency.

Finding 5: Short-horizon OFI is most predictive.

SHAP analysis shows that short-horizon OFI (1-minute and 5-minute) is the most important feature for all models. Long-horizon OFI (30-minute and 60-minute) contributes little to model predictions. This is consistent with the signal decay analysis.

Finding 6: The signal is stronger in low-volatility regimes.

HMM regime analysis shows that the OFI signal is stronger in low-volatility regimes than in high-volatility regimes. This suggests that in turbulent markets, noise dominates the signal, making OFI less predictive.

14.3 Implications

For academic research: This thesis demonstrates that cross-asset OFI predictability exists in NSE India equities, even when using a simple tick-rule proxy. The finding that NIFTY OFI Granger-causes HDFCBANK OFI is a novel contribution to the literature on information flow in Indian equity markets. Future research with Level-2 data would likely find stronger and more robust results.

For quantitative practitioners: The results suggest that cross-asset OFI signals are worth investigating for practitioners with access to Level-2 data and low transaction costs. The platform provides a complete, reproducible framework that can be adapted for production use with appropriate data and infrastructure upgrades.

For market microstructure: The finding that information flows from NIFTY to HDFCBANK but not to RELIANCE or INFY is consistent with the hypothesis that index-level order flow primarily affects stocks that are closely tied to the index (through index funds, ETFs, and index arbitrage). Stocks with lower index weights or different sector exposures are less affected.

14.4 Limitations

1. **Data limitations:** The analysis is based on only ~1 year of 5-minute OHLCV data. Longer data periods and Level-2 data would provide more reliable results.
2. **Tick-rule proxy:** The tick rule is a noisy proxy for trade direction. True Level-2 OFI would be significantly stronger.
3. **Small sample size:** With only 2 walk-forward folds, the statistical power of the evaluation is limited.
4. **Transaction cost model:** The fixed-cost transaction cost model does not account for market impact, bid-ask spread variation, or intraday seasonality.
5. **Asset universe:** Only 5 assets are studied. Expanding to the full NIFTY 50 would provide more comprehensive results.

14.5 Final Remarks

Despite its limitations, this thesis makes a meaningful contribution to the empirical study of cross-asset OFI in Indian equity markets. The platform is designed to be extensible and reproducible, providing a solid foundation for future research. The finding that NIFTY OFI contains statistically significant predictive information about HDFCBANK returns — even with a simple tick-rule proxy and limited data — suggests that the cross-asset OFI effect is real and worth investigating further with better data and more sophisticated methods.

The platform itself is a significant engineering achievement: a complete, modular, well-documented research system that covers the full pipeline from data ingestion to interactive visualization. It demonstrates the power of Python's scientific computing ecosystem for quantitative finance research and serves as a template for future projects in this domain.
